Bearing in mind the fact that the gonococcus of Neisser may remain dormant in these passages for months, and, as maintained by some observers, for years, incapable of a further inoculation of the seemingly immunized patient, but capable of exciting the most acute and injurious inflammation in an innocent victim, it becomes a matter of the greatest importance to subject to most careful study the external genito-urinary passages where an infection has once existed. It has been demonstrated that an artificial urethritis, such as that which nitrate of silver produces, will develop the dormant gonococci and cause their presence in the discharge.

Keys and Chetwood, in their excellent volume on venereal diseases, place well-deserved emphasis upon the value of the Gram test for recognizing these organisms. They properly insist that the diplococci should be of the recognized size and have within the protoplasm of the pus corpuscle their proper shape and arrangement and remain negative to Gram's staining. Even when cultures are made to demonstrate the specific organisms beyond all doubt, resort should still be had to the Gram staining as a final means of identification.

In cases of pyelitis, many of the difficulties which for-

*Dr. Jeffreys, the director of the laboratory in the New York Polyclinic, employs the following differential stain:

Use Gram's stain followed by a contrast stain, such as Bismarck brown. To prepare this stain proceed as follows:

Prepare aniline water by emulsifying 8 drops of aniline oil in about 10 cubic centimetres of water. Filter through a wet filter. To this aniline water add about one tenth its bulk of a saturated alcoholic solution of gentian violet. Stain smear with this "aniline water gentian violet" one or two minutes. Wash in warm water and then immerse in Gram's solution for one minute. The formula for this solution is as follows:

Iodine	1 gramme;
Iodide of potassium.....	2 grammes;
Water	300 c.c.

Thoroughly wash in 95-per-cent. alcohol until no more blue appears to wash out; then wash in water. Counterstain for one minute with a saturated solution of Bismarck brown in 3-per-cent. aqueous solution of carbolic acid. Wash. dry, and mount in balsam. After this treatment, pseudo-gonococci should be stained violet, and gonococci should be brown.

*Kelling's test consists of 5 c.c. of the filtrate diluted to 50 c.c. with distilled water, to which one or two drops of official 5-per-cent. solution of the perchloride of iron are added. The yellowish-green tinge indicates the presence of lactic acid.

†To 10 c.c. of the filtered contents add 3 c.c. of glacial acetic acid, and extract the coloring matter of the blood by shaking with 5 c.c. of ether. This turns the ether extract brown. When this discoloration does not take place there is no blood. To carry the demonstration further, to the brownish decanted ether extract, 10 drops of fresh tincture of guaiac with a few drops of peroxide of hydrogen are added. After vigorously shaking, the mixture becomes clear blue if blood is present.

merly stood in the way of differential diagnosis between renal calculi, simple pyogenic pyelitis, or the presence of tuberculous disease in this organ are now overcome by the careful methods of the laboratory.

The presence of the bacilli of tuberculosis in one or both kidneys, even when they are exceedingly infrequent in the discharge, can be demonstrated in urine drawn by urethral catheterism or by the more simple process of bladder segregation, when the suspected organisms are with other detritus thrown down by the centrifuge. The carbolfuchsin stain decolorized with 5-per-cent. sulphuric acid brings out in brilliant red the outlines of the bacilli of tuberculosis, while the addition of 95-per-cent. alcohol decolorizes the smegma bacillus, and thus eliminates this possible source of error to any but the more expert laboratory workers.*

In the effort to arrive at the general condition of a patient, the chemical, microscopical, and bacteriological study of the urine is only second in importance to that of the blood, and when we consider the additional and exact information which can thus be obtained concerning any pathological process at any point in the urinary tract, the value of this analysis is very materially increased. A careful study of the urine is always indicated before determining what anæsthetic it is safest to employ in the operation to be undertaken. When there is no important lesion of the heart, either in its valvular mechanism or in the blood supply and nutrition of its muscular walls, few surgeons, I hold, would employ ether in a protracted operation in which there was any suggestion of an acute nephritis, or in certain chronic forms of Bright's disease.

It is commendable practice to study through several days the quantity of urine passed, keeping accurate measurement, as well as making a qualitative analysis of that which is passed under conditions as nearly as possible similar to those to which the patient had been subjected before coming under observation, and then under conditions of rest, with proper alimentation and the free opening of the alimentary canal with calomel and Carlsbad salts (which agents in my experience most readily do away with fermentation and the production of gases in the bowels); to note the changes which occur in excretion.

The presence of oxaluria is, in my opinion, a contra-indication to a serious surgical operation, for the reason that it is pathognomonic of a disturbed nutrition due to insufficiency of the digestive fluids, and to fermentative processes in the intestinal tract.

An excess of *uric acid*, evident in the rosettes or rhombic or quadrate crystals (one sixth objective), found

The following process is used at the Polyclinic laboratory in determining the presence of the tubercle bacillus in the urine and feces. The sediment is thrown down in the centrifuge, the smear dried slowly over the Bunsen burner and stained with carbolfuchsin, which is then warmed over the Bunsen burner for three or four minutes without being dried. Then wash with water and decolorize with 5-per-cent. sulphuric acid, and again wash with water. After this add 95-per-cent. alcohol, which decolorizes the smegma bacillus and again wash in water, counter-stain with methylene blue, and dry. With the $\frac{1}{2}$ th oil immersion, the clusters of tubercle bacilli are readily seen.

in the urine *which has not been passed* more than three or four hours, has also a pathological significance scarcely less than that of oxaluria. It indicates a condition of defective nutrition which is part of the gouty or rheumatic diathesis, predisposes to chronic nephritis, and is one of the symptoms of various acute inflammatory processes, of leucæmia, cirrhosis of the liver, gastro-intestinal catarrh, and is often present in diabetes mellitus.

The chemistry and microscopy of the urine further inform us when ammoniacal decomposition of the urine is taking place within the bladder, suggesting insufficiency of this organ due to obstruction of the urethra or to atony of the bladder muscle. The large rhombic masses or stellate and cross-shaped rosettes of the triple phosphates only exist in these abnormal conditions of the bladder, and with the brownish-colored thorn-like crystals or urate of ammonium are important aids to diagnosis.

The presence of epithelia from the various portions of the urinary or genito-urinary tract, of spermatozoa, and of various bacteria chiefly pyogenic in character, is further and well-recognized evidence of the value of the microscope in surgical diagnosis. In rarer instances, the hooklets of echinococcus, the embryos of filaria, and the ova of *Hæmatobium Bilharzii* are thus discovered in the urine. The writer has been able once to demonstrate the presence of the eggs of the last-named parasite in the bloody urine of a missionary in Africa, where he had by long residence acquired the disease.

From the laboratory we are taught the well-known tests for albumin and sugar by which all sources of error may be eliminated in determining not only their presence but the quantitative analyses as well. The pathological conditions in which these substances are excreted are at times exceedingly grave, and it is of vital importance that their presence be discovered so that timely and judicious treatment may be instituted, or operation avoided which under such unfortunate conditions would be invariably fatal.*

In glycosuria the surgeon must know whether he is dealing with what Pavy designates as alimentary diabetes, in which the sugar eliminated by the urine is derived solely from the food as result of defective carbohydrate assimilation, or whether that almost hopeless condition of composite diabetes in which abnormal disintegration is taking place is present.

No less important is the estimate of the amount of urica which is being eliminated in a given quantity of

*To determine the presence of albumin, the nitric acid and heat test is classical and reliable. The simplest quantitative analysis as recommended by Hare is to fill the tube for the centrifuge to the 10 c.c. mark with urine, to which is added 2½ c.c. of potassium ferrocyanide solution (one part to ten): 1½ c.c. of acetic acid is also added. After mixing the fluids well the centrifuge is rotated until the albumin is precipitated. Every 1-10th c.c. mark on the tube represents 1 per cent. by bulk of albumin; that is, if the albumin extends up to the 3½ c.c. mark the albumin amounts to 35 per cent.

Fehling's test in the demonstration of sugar and the quantitative analysis by means of yeast fermentation is another important laboratory process, without recourse to which the surgeon in a certain group of cases cannot satisfactorily work.

urine. Employing the simple apparatus of Doremus with the sodium hypobromite solution,* within a few minutes' time, by the evolution of nitrogen gas in the presence of this, the amount of urea which is being carried off by the kidneys is readily demonstrable.

Non-parasitic chyluria (that form not due to the presence of filaria) is a rare affection, but it does exist, the fluid coagulating almost like jelly. In these conditions the microscope shows little that is pathological excepting some minute granules and oil droplets similar to those in milk. (Osler.)

The presence of blood in the urine, even in the most minute quantities, can in almost all cases be recognized by the microscope, and in those exceptional instances of hæmoglobinuria in which the corpuscles have disappeared, the blood crystals of Teischmann may be recognized by the addition of a drop of strong acetic acid to a few drops of urine placed upon a watch-glass. For this condition of blood pigment in the urine in which the blood-cells are absent, Osler suggests the name methæmoglobin. He further states that when granular pigment or darkly pigmented urates or fragments of blood-disks do not point clearly to the presence of blood, the two absorption bands of oxyhæmoglobin, and, more commonly, the three absorption bands of methæmoglobin, of which the one in the red near G is characteristic, may be determined by the spectroscope. In general, however, the red and white blood corpuscles and filaments of clot are clearly recognizable with the one sixth objective. Even without the microscope the presence of a very minute quantity of blood distributed through the urine can be recognized by Heller's test of adding a few cubic centimetres of urine to a drop or two of strong solution of caustic soda and boiling the mixture. If blood is present, a bottle-green color is produced and the phosphates fall to the bottom of the test-tube in fine flakes, tinged brownish-red by the coloring matter of the blood. (Hare.)

When blood is found in the urine as a complication of papilloma of the bladder, particles of the broken-down tumor are very frequently found in the urine, and under the microscope the epithelial elements of this neoplasm are easily recognized and point clearly to the source of the hæmorrhage. In hæmorrhage from the kidney substance blood casts tell unmistakably of its source.

Chemistry demonstrates in the urine the presence of indican, or indoxyl sulphate of potassium, a product resulting from the decomposition of albuminous products in the intestinal tract under the influence of bacteria. It is always suggestive of persistent constipation, is found

in obstruction of the intestinal canal, in carcinoma of the liver or stomach, and in peritonitis, and is one of the symptoms of pernicious anæmia. Urine containing this substance, if treated with two or three times its volume of hydrochloric acid, turns a violet color.

A careful analysis of the various casts found in the urine under different conditions is of inestimable value. Blood casts indicating not only hæmorrhage from the kidney, but acute inflammatory conditions, and casts composed of pus corpuscles and studded with micrococci suggesting pyelonephritis, are most valuable results in laboratory research. It also tells us of the existence of granular casts which indicate a chronic or subacute inflammatory process in the substance of the kidney, which is accentuated when fatty casts are found, and that hyaline casts have a grave significance, as they are most frequently associated with chronic interstitial nephritis, and that the waxy variety is very common in chronic suppurative processes, usually in the bones and joints.

To-day one of the most attractive subjects of laboratory research is the blood, and although hæmatology is practically in its infancy many valuable discoveries have already been made, and in the proper study of a patient a knowledge of the blood is as essential as that of the urine. It may throw no light upon many cases, but the reward will be tenfold in that particular instance where the diagnosis is made definite and clear. It is necessary to know the normal blood thoroughly by constant practice in order to recognize the abnormal changes which may be present in a given case, and I can think of no more useful way of spending the time not taken up by practice than by going over these important features of laboratory technique.

A knowledge of hæmatology enables the surgeon to detect any form of anæmia and to determine whether it is a type of blood impoverishment which can be corrected, or whether it is of the graver or more pernicious forms which would either preclude an operation, or, if this were absolutely necessary, would enable him to announce to those entitled to information the gravity of the outlook. In ordinary practice it is not always essential to differentiate between a pernicious anæmia and a leucæmia, or whether this latter condition is present in the lymphatic or splenic-myelogenous form, for the reason that all of these graver varieties call a halt to operative measures when these can be avoided. But the anæmia which comes from malnutrition or malaria or chlorosis can be positively diagnosed by a study of the blood.

The richness of the hæmoglobin may in a fair measure be determined by the comparative color test of the blood in proper solution, as observed through von Fleischl's hæmometer. When a low percentage of hæmoglobin is present, it is an indication to avoid any operative shock until the impoverished condition of the blood can be corrected by proper nourishment, by rest, or by medication, when this is positively indicated. This also sug-

*Solution A, bromine and sodium bromide each 125 grammes, water 1,000 c.c. Solution B, sodium hydrate 400 grammes, water 1,000 c.c. Take of A and B each one part, water three parts. They are only to be mixed when needed for use. After the tube has been filled with the solution the pipette is filled with urine to the one c.c. and the point carefully introduced beyond the bend. The urine in the pipette is then expelled by compression of the bulb, care being taken not to force any air into the tube.

gests the aid of the microscope in a further investigation as to the condition of the corpuscular elements of the blood. It is advised by Mikulicz never to operate when the register of the hæmometer shows less than 35, and it would probably be safer to place the standard ten or fifteen points higher. Even in the simple forms of anæmia, the degenerative changes in the blood elements, especially in the red cells, are easily recognized, and are full of valuable suggestions.

When the red cells are near the normal count (about 6,000,000 to the c.c.) they may still show certain characteristic deformities of individual cells (poikilocytosis) as well as variations in size in the presence of microcytes and macrocytes which appear in the field, and which are not seen in the normal blood. If the red cells are paler in color than normal, if they undergo crenation or breaking at the edges, and do not form rouleaux, it is evident that anæmia is present.* The danger signals are still further in evidence when nucleated red cells (normoblasts) appear, and when there is added to these either the giant red cells (megaloblasts) or abnormally small microblasts, the condition is still more serious, since these corpuscles never exist in the normal blood.†

Hæmatology further enables us to differentiate with reasonable precision between chlorosis and pernicious anæmia. In the former, though pale in color, the blood coagulates rapidly, while in the latter coagulation takes place slowly and the red corpuscles do not tend to the formation of rouleaux. The red cells in chlorosis (which are smaller and paler than normal and are frequently deformed) vary from 4,000,000 to 2,000,000, rarely falling as low as 1,000,000, while in pernicious anæmia, in which the average diameter of the red cells is increased, the count rarely rises above 1,000,000, and is often below this. Cabot gives 1,000,000 as the average number per cubic millimetre. The white cells are also diminished, varying from 4,200 to as low as 500, with lymphocytosis as a prominent feature. Megaloblasts are found in both conditions, but while plentiful in pernicious anæmia are rarely noticed in the milder disease, chlorosis. The more megaloblasts in pernicious anæmia, the more hopeless the case.

The surgeon would be extremely unfortunate to fail in the recognition of these often obscure lesions, and, if possible, to correct them before subjecting his patient to the severe ordeal of an operation. In the early recognition of septic processes—chiefly pyogenic—surgery can no longer disregard the value of the blood count, especially the estimation of the leucocytes.

The relative number of leucocytes in a given quantity of blood, or their proportion to the red corpuscles, can be readily determined by the use of the Thoma-Zeiss apparatus, which, as is well known, consists of two pi-

The average red corpuscle (normal) is seven micromillimetres in diameter.

†A normoblast is a nucleated red cell not over 10 mm. in diameter, with a nucleus of not more than one half the diameter of the same.

ettes, one for the red and one for the white, with a well-outlined and peculiarly constructed slide or counting apparatus, and employed with the ordinary one sixth laboratory objective. The differentiation by the use of the Daland hæmatocrite is not considered sufficiently exact to be satisfactory in the hands of the majority of hæmatologists. It is essential in making these differentiations to bear in mind the normal conditions that at the sea level the average number of red cells per cubic millimetre is 5,000,000 in men, and 4,500,000 in women, and 6,000,000 in the young and more vigorous adults, while the white cells average about 7,500 per cubic millimetre for each sex.

Certain conditions not considered normal influence the number of leucocytes, since in the latter months of pregnancy they are moderately increased, and after parturition and during the early weeks of lactation a leucocytosis may be present without pathological significance. After hæmorrhage the leucocyte count is increased, and in diphtheria, erysipelas, trichiniasis, all extensive forms of endometritis, and all acute pyogenic processes leucocytosis exists except in those cases where the vitality of the individual has been overwhelmed by the severity of the septic process, under which condition the leucocytes no longer respond to the demand for the protection of the tissues, and are not present in the superficial blood in even normal proportions. It is probable that the application of this knowledge is more profitable at present in a study of the various lesions of the abdominal and thoracic organs. We know that in a certain proportion of cases of infection, temperature does not always indicate the increasing gravity of the lesion, while the degree of sepsis can be in great measure determined by the leucocyte count. In impaction of fæces, extra-uterine pregnancy, floating kidney, gall-stone colic, renal colic, ovarian neuralgia, intussusception, volvulus, internal hernia, twisted pedicle, etc., there is no leucocytosis unless complicated with an acute septic process. In abscess of the liver the leucocyte count ranges from 12,000 to 48,000, while there is a well-marked increase in all the septic pyogenic processes of the lungs and the pleura.

In osteomyelitis the leucocyte count ranges, as a rule, from 15,000 to 25,000, and at times higher. Since, in the early stages of this disease, it is at times difficult by subjective symptoms to differentiate between rheumatism and gout, the leucocyte count is invaluable in demonstrating at once the pyogenic process.

In that very rare disease, trichiniasis, the leucocytes register sometimes as high as 30,000, but the special feature is the presence of a large number of eosinophile cells, sometimes as high as 50 per cent., and in rare cases 67 per cent. of the total number of leucocytes being this form of corpuscle. A very considerable number of cases have been reported within the last year in which the diagnosis had been determined by the presence of eosinophiles.

Not only can the presence of the *Plasmodium ma-*

larix be recognized in the red blood cells, but hæmatology is already able to determine between the different varieties of the malarial parasite. It has been shown that the tertian organism takes forty-eight hours to develop and undergo sporulation; the quartan seventy-two, while the æstivo-autumnal passes through irregular phases, varying from forty-eight hours to several days.

We are enabled to demonstrate also the presence of the spirochete of relapsing fever discovered by Obermeier in 1873. Although the cork-screw, or spiral, threads are rarely seen unless the blood is examined in the height of the fever paroxysm, diplococcus-shaped bodies, believed to be the spores of this organism, are found in the periods of remission.

The time allotted has permitted hardly more than a suggestion of the methods of laboratory research applicable in the daily routine of surgical practice. To me the moral of the lesson is that the *science* and *art* of surgery are inseparable.

THE PROGRESS AND TENDENCY OF HYGIENE AND SANITARY SCIENCE IN THE NINETEENTH CENTURY,

BEING THE ORATION IN STATE MEDICINE BEFORE THE
FIFTY-SECOND ANNUAL MEETING OF THE AMERICAN
MEDICAL ASSOCIATION, AT ST. PAUL, JUNE
4, 5, 6, AND 7, 1901.

BY GEORGE M. KOBER, M. D.,
WASHINGTON, D. C.,

PROFESSOR OF HYGIENE, GEORGETOWN UNIVERSITY.

HYGIENE is a department of medicine whose object is the preservation and promotion of health, and deals, therefore, with all the factors likely to influence our physical welfare. It is not an independent science, but rather the application of the teachings of physiology, chemistry, physics, meteorology, pathology, sociology, epidemiology and bacteriology to the maintenance of the health and life of individuals and communities. The subject is very properly divided into personal and public hygiene. In the former the doctrines are applied to individuals, in the latter to communities and States.

This branch of medicine has received such an impetus within the last few decades that many persons regard it as of modern origin; such, however, is not the case, for on turning to early history we almost invariably find that the health of the population has been made a subject of legislation. Hygiene was practised by the Egyptians, the old Indians and Hebrews, and a study of the habits of the primitive peoples shows that a desire to prevent disease is innate to all men.

The Greeks and Romans paid special attention to the physical culture of their youth; they also paid much attention to the water supply, and Athens was provided with sewers at an early period of her history.

The teachings of Hippocrates, 400 B. C., doubtless

bore many fruits, and whether it is true or not, as stated by Galen, that he ordered, during a pestilence at Athens, aromatic fumigation and large fires in the streets, we have at least his writings on air, water, soil, habitations, and occupations, and his views of local and seasonal influences on sporadic and epidemic diseases. In Homer's *Odyssey* reference is made to Ulysses purifying his house with burning sulphur, and Aristotle, in his *Politica*, shows his sanitary acumen when he says: "The greatest influence upon health is exerted by those things which we most freely and frequently require for our existence, and this is especially true of water and air."

The Romans, amidst their military operations, found time to construct the Cloaca Maxima about 2,400 years ago, which not only served for the removal of refuse, but also helped to drain many of the marshes, and still constitutes the principal sewer of modern Rome. Aqueducts were made to cover miles upon miles of the surrounding plains, and their splendid ruins, many of which have been restored and are now used for their original purpose, attest the munificence and abundance with which the first of sanitary requisites was supplied to the Eternal City. It is stated that between 400 B. C. and 180 A. D. about 800 public baths were established, among them the Thermæ Caracallæ, which alone would accommodate 3,000 bathers at one time.

During the reign of the Cæsars attempts were made to drain the Pontine marshes; sanitary officials and physicians to the poor were appointed and homes for poor girls and orphans were established. In the meantime the true spirit of Christianity asserted itself, and we read of the establishment of hospitals so early as the fourth century; these were speedily followed by infant and orphan asylums and homes for the poor and incurables. During the Middle Ages sanitation received a decided check, ignorant and brutal prejudices appear to have been the ruling spirits, and for many reasons it was the most insanitary era in history.

PESTS AND INSANITARY CONDITIONS OF THE MIDDLE AGES.

About this time most of the towns in Europe were built in a compact form, surrounded with walls; the streets were narrow and often winding for defensive purposes, shutting out light and air from the houses. The accumulation of filth was simply frightful. Stables and houses were close neighbors, human filth was thrown on the streets or manure heap. The dead were buried within the churchyards. Sewers and aqueducts having been permitted to fall into disuse, the inhabitants were compelled to resort to wells with polluted subsoil water. All the conditions were favorable for the spread of infectious diseases, and in the fourteenth century alone the Oriental or bubonic plague, according to Hecker, carried off one quarter of the population of Europe, or over twenty-five million victims.

Although this disease had been described as early as

the third century, B. C., a lamentable state of ignorance is shown, when we remember that the majority of people regarded the plague as the dispensation of God's providence, an evidence of divine wrath, which they hoped to allay by all sorts of self-inflicted punishments, and the passion plays of Oberammergau and elsewhere originated about this time. Others accused the Jews of being the cause, and hundreds were burned at the stake until Pope Urban IV placed them under his special protection. The Faculty of Paris attributed the epidemic to the conjunction of planets on a certain day in 1345, and the Faculty of Leipzig, with equal gravity, asserted that it was connected with earthquakes, unseen waves of air, inundations, etc. Venice alone of all Europe took a sensible view of the matter, and for the first time in history, in 1348, appointed three guardians of public health, and the rules adopted later to isolate infected houses and districts for forty days have given rise to the term quarantine—from *quaranta giorni*.

The repeated invasion of the Oriental pest appears to have everywhere compelled some sanitary efforts, and an imperial decree, in 1426, required the appointment of city physicians throughout Germany, whose duty it was to adopt preventive measures. A city ordinance of Nürnberg, in 1562, gives detailed directions as to the quality of bread, beer, and wine offered for sale, the cleaning of streets and houses, the disposition of infected clothing and bedding, the fumigation with sulphur and straw of pest-houses, etc.

In 1685, Prussia established a central medical bureau, and appointments of health-officers and privy medical counsellors were made, whose duties consisted in advising the men entrusted with the care of the government on matters relating to public health, and some of these titles are still in vogue in Europe. At the beginning of the eighteenth century, Prussia, upon being threatened with an invasion of the bubonic plague from Austria, created the Collegium Sanitatis, popularly called the Pest College, which was really the beginning of the present State board of health. In 1762 a sanitary council was established in every Prussian province for the prevention of disease among man and animals. About the same time sanitary improvements in the way of widening streets for the purpose of supplying more air and light to the habitations, and better methods for the collection and removal of the wastes of human life, were introduced, but, broadly speaking, at the close of the seventeenth century the habits of the people in Europe were generally filthy, and in striking contrast to those observed among the most untutored savages of the present day.

In Madrid, we are told by Barcome, in his *History of Epidemics*, that "not even a privy existed in 1760. It was customary to throw the ordure out of the windows at night, and it was removed by scavengers the next day. An ordinance having been issued by the king that every householder should build a privy, the people violently opposed it as an arbitrary proceeding, and the physi-

cians remonstrated against it, alleging that the filth absorbed the unwholesome particles of the air which otherwise would be taken into the human body. His majesty, however, with commendable zeal, persisted, but many of his citizens, in order to keep their food wholesome, erected privies close to their kitchen fire-places."

With such unsanitary conditions we need scarcely be surprised that the mortality in towns was greater than their birth-rate, and that the city population had to be recruited continually from the country. Toward the close of the eighteenth century many sanitary reforms were effected, however, especially in connection with infant and orphan asylums, and the management of schools and prisons. Of special importance is the brilliant discovery, or rediscovery, of vaccination by Jenner in 1796.

PROGRESS OF SANITATION IN THE NINETEENTH CENTURY.

The nineteenth century can boast of many advances in hygiene, particularly since the European invasion of cholera in 1830. The English towns which had been visited by this disease and those fearing similar scourges were willing to profit by their sad experience, and freely instituted sanitary reforms in the establishment of sewers, public water supplies, sanitary homes, etc.

The example of England was followed by all civilized nations, with similar results. The efforts of sanitation, as taught by Dr. Parkes, were demonstrated during the Crimean war and, as beautifully expressed by Virchow during our civil war, reached "the highest point in humane efforts ever attained in a great war," and, we may proudly add, have even been excelled during our late Spanish-American war.

PROGRESS OF SANITATION IN THE UNITED STATES.

While the people of the United States were not slow in adopting and originating sanitary measures of great value, our ideas of personal liberty, guaranteed to us by the Constitution, evidently prevented early legislation in matters of public health, for fear that such legislation might affect the personal habits of the citizen and lessen his freedom of action. Dr. Samuel W. Abbott, in his masterly exposition of *The Past and Present Condition of Public Hygiene and State Medicine in the United States*, records, however, the gratifying fact that the early colonists recognized the need of preserving their records, which constitute the foundation stone of public hygiene, by enacting a law in 1639 "that there be records kept of the days of every marriage, birth, and death of every person in this jurisdiction."

The importance of vital statistics is not fully appreciated at the present day, and yet, as remarked by Dr. Billings, "when we wish to study the healthfulness of a city, whether it is getting better or worse, or judge correctly the effect of certain sanitary laws, we should not only know the number of deaths, but also the amount

and character of the prevalent disease, together with accurate information as to the number of population at different ages." It is a matter of regret, therefore, that even now only ten States, Connecticut, Delaware, Maine, Massachusetts, Michigan, New Hampshire, New Jersey, New York, Rhode Island, and Vermont, have anything like a satisfactory system of vital statistics.

According to Abbott: "Up to the close of the eighteenth century and for several decades of the nineteenth, almost the only health legislation which was enacted in the different States in the Union consisted in a few laws relating to smallpox, since this pestilence was scarcely ever absent for many years at a time from any city or village, till after the general introduction of vaccination."

Dr. Waterhouse, of Cambridge, having secured a supply of vaccine lymph from Dr. Jenner, introduced vaccination in Boston in 1800, and Dr. Seaman in New York in 1801. In the same year President Jefferson received some virus from Dr. Waterhouse and was vaccinated by Dr. Grant, of Georgetown.

The invasion of cholera from Canada in 1832, and the epidemic of 1848-1849 here, as in Europe, aroused public interest in sanitary reforms, and the Legislature of Massachusetts in 1849 appointed a commission to make a sanitary survey of the State, and we are told by Dr. Abbott "that this was done none too soon, for in that year the general sanitary condition of the State, as shown by the report of the commission, was deplorable and the death rate unusually high. Only a few towns had then introduced public water supplies. Cholera was beginning to appear again and dysentery and other infectious diseases were more destructive than they had been for many years."

HEALTH BOARDS.

New Orleans having lost 8,000 victims of cholera in 1832 out of a population of about 55,000, and anxious to maintain a quarantine, secured the enactment of a law in 1855 for the establishment of a State Board of Health; in 1869 a more comprehensive board was established in Massachusetts, followed in 1870 by California, since which time nearly all of the States and Territories—forty-two in number—have followed the example. *Pari passu* with, and in many instances preceding, the establishment of State Boards of Health, sprung into existence our local Boards of Health, who adopted measures for the control and restriction of infectious diseases, for the abatement of local nuisances, for the sanitary inspection of the food supply, schools, public buildings and institutions and tenements; street cleaning and removal of refuse, registration of vital statistics, supervision of burials and of municipal water supply, sewerage, and sewage disposal, care of bathing establishments, regulation of offensive trades, etc.

EFFECTS OF VOLUNTARY ORGANIZATION ON SANITATION.

In September, 1872, the American Public Health

Association was organized; in 1873, the Section on State Medicine of the American Medical Association was created; since then the American Climatological Association, the Sanitary Council of the Mississippi Valley, the American Sanitary Association, and the American Health Resort Association have been organized, and numbering, as they do, among their members some of the best minds in the profession, much good has been accomplished by these bodies and the so-called "sanitary conventions," in moulding public opinion and in framing and recommending health laws. There is no doubt, however, that all these organizations were stimulated into existence by the lofty tenets of our Code of Ethics,* in which the duties of the profession to the public were prescribed as early as 1847.

Indeed, the American Medical Association, according to Dr. N. S. Davis, Sr., gave prominent attention to State medicine and sanitation from its first meetings. At the second annual meeting, in 1849, standing committees were appointed on forensic medicine and on hygiene and reported annually on these topics and on meteorology, medical topography and epidemic diseases until 1860, when work in sections was commenced. Dr. A. N. Bell, of New York, delivered the first address on State medicine in general session of the association in 1874, followed, in 1875, by Dr. N. I. Bowditch, of Boston.† In this connection, I may say that there is need of reliable information on the geographical distribution of diseases like goitre, cretinism, etc., and county medical societies would contribute much to the common fund of knowledge by placing on record information of this character.

NATIONAL BOARD OF HEALTH.

The cholera epidemic of 1872 and 1873 resulted in the appointment of a commission by Congress. This, together with the yellow-fever epidemic of 1878 in the Southern States, affecting, according to Sternberg, over 74,000 persons, with 16,000 deaths, called attention to the necessity of some central sanitary organization. In March, 1878, Congress created a national board of health, whose duty it was to make investigations into the causes and means of prevention of contagious and infectious diseases, to indicate measures of national importance and to be a centre of information for all matters relating to public health. For want of appropriation this important body has ceased to exist, and since 1883 the duties relating to international and inter-State

*Article 1, paragraph 1, reads: As good citizens, it is the duty of physicians to be ever vigilant for the welfare of the community and to bear their part in sustaining its institutions and burdens; they should also be ever ready to give counsel to the public in relation to matters especially appertaining to their profession, as on subjects of medical police, public hygiene and legal medicine. It is their province to enlighten the public in regard to quarantine regulations, the location, arrangement and dietaries of hospitals, asylums, schools, prisons and similar institutions; in relation to the medical police of towns, as drainage, ventilation, etc., and in regard to measures for the prevention of epidemic and contagious diseases, and when pestilence prevails it is their duty to face the danger and to continue their labors for the alleviation of the suffering, even at the jeopardy of their own lives.

†Information kindly furnished by Dr. N. S. Davis, Sr., and Dr. George H. Simmons, letter of April 18, 1901.

quarantine have been discharged by the surgeon-general of the United States Marine-Hospital Service; his bureau, apart from the management of hospitals and stations for the care of sick and disabled seamen of the merchant marine, has also undertaken the collection and dissemination of mortality statistics and sanitary information, scientific investigation into the causes of disease, the physical examination of immigrants under the law, excluding those affected with contagious disease—service in the office of consuls at foreign ports to assure the accuracy of bills of health—and other miscellaneous duties. Since Congress has failed to act upon the President's repeated recommendation and the petition of numerous medical societies for the creation of a national health establishment, there is no good reason why the scope of duties and powers exercised by the Marine-Hospital Service should not be enlarged. Indeed, the last Congress appropriated sufficient money for the erection of a laboratory "for the investigation of infectious and contagious diseases and matters pertaining to the public health," which marks the beginning of a new era in national sanitary legislation.

NATIONAL AND INTERNATIONAL QUARANTINE.

The question of an efficient system of national and international quarantine against Asiatic cholera, yellow fever, smallpox, typhoid fever, bubonic plague, and leprosy has engaged the attention of sanitarians for years, especially since it has become known that these diseases, particular cholera, are generally carried along the highways of travel and commerce. Special efforts were made after the completion of the Suez Canal and other rapid-transit facilities, to guard Europe from the invasion of cholera from India, and since 1892 these efforts have been quite fruitful. At all events, with efficient quarantine regulations involving inspection of vessels, passengers, and crew, the detention of the sick and disinfection of all others, including personal effects, cargo, and vessels, and proper notification, we have been enabled to keep these diseases from our shores, and, if other nations do the same, they should be restricted to their original home. General Wyman's plan, as outlined in his address before the Pan-American Medical Congress, contemplates an international system of sanitation; while his proposition refers especially to yellow fever in the Western Hemisphere, it is equally applicable to the home of cholera and the Oriental plague.

In the light of the recent researches by Reed and Carroll as to the transmission of yellow fever by means of mosquitoes, our views concerning quarantine and disinfection in this disease may have to be modified, but in the meantime the fight against the mosquitoes will go on; whether this will be effectually accomplished by insecticides and screens, or the more rational method of drainage of the soil, remains to be seen; in either event malarial countries will likewise be benefited.

HAS HUMAN SUFFERING BEEN MITIGATED AND HUMAN LIFE GREATLY PROLONGED BY EFFORTS IN SANITATION?

Our answer is an emphatic "Yes." Professor Finkelnburg, of Bonn, estimates that the average length of human life in the sixteenth century was only between 18 and 20 years; at the close of the eighteenth it was a little over 30 years, while to-day it is over 40 years; indeed, the span of life since 1880 has been lengthened about six years, as shown by statistics, in Mulhall's *Dictionary of Statistics* (Fourth Edition, London, 1899).

The mortality of London between 1660 and 1678 was 80 per 1,000 of inhabitants; from 1728 to 1780, 51 per 1,000; from 1801 to 1835 it was still 29, while at the present time it averages between 17 and 19 per 1,000.

INFLUENCE OF SEWERS AND PUBLIC WATER SUPPLIES.

Without underestimating the brilliant achievements of Jenner's discovery of vaccination in 1796, which as a preventive measure has saved millions of lives, no two factors have contributed so much to the general result as the improvement of the air we breathe and the water we drink. Indeed, we have ample evidence that, with the introduction of sewers and public water supplies, the general mortality in numerous cities, during the past forty years, has been reduced fully one half, the good effects being especially shown by a marked decrease in the number of cases of typhoid fever, diarrhoeal diseases, and consumption. The vital statistics of Great Britain furnish the proof. The mortality at Salisbury within the last thirty years has been reduced from 40 to 16 per 1,000; at Dover, from 28 to 14 per 1,000; at Rugby, from 24 to 10 per 1,000; at Croydon, from 28 to 15 per 1,000; and at Matlock, from 18 to 9 per 1,000.

The history of every sewered city shows a lessening of the typhoid death rate subsequent to the construction of the sewers, and that the typhoid rate is always higher in sections supplied with privy pits and box privies than in the houses connected with sewers. In 1895 the speaker pointed out that typhoid prevailed in the city of Washington and suburbs in 1 of 81 houses with privies, and in only 1 in 149 of those connected with sewers, and the health officer of Nottingham has since then presented similar evidence. The only reasonable explanation for this is that sewers carry away the filth that otherwise would contaminate the soil and ground water, but even if there were no wells, these makeshifts are still a source of danger in so far as they favor the transmission of the infection by means of flies, nor can the possibility be ignored that the germs in leaky or overflowing boxes may reach the upper layer of the soil, and, with pulverized dust, gain access to the system. This conclusion, and the agency of flies in carrying the germs from box privies and other receptacles from typhoid stools to the food-supply, was enunciated in my report in

1895 and appears to have found ample support in the experience of the late Spanish-American war.

INFLUENCE OF IMPROVED WATER SUPPLIES.

According to Dr. Abbott, the number of towns in the United States before 1800 having a public water supply was only 16, supplying about 2.8 per cent. of the existing population; in 1850 there were only 83 public water works, supplying about 10.6 per cent. of the census population; in 1897 the total number was 3,196, supplying about 41.6 per cent. of the population.

A summary of the evidence on this subject reveals the significant fact that cities, both at home and abroad, in which there has been the most marked decrease in typhoid fever death rate, are those in which a pure supply has been substituted for a preexisting contaminated one. Thus, for example, the typhoid fever death rate in Boston in 1846-1849 was still 17.4 per 10,000; in 1890-1892 it had fallen to 3.2 per 10,000, the city having in the meantime expended \$25,000,000 on its water supply. The typhoid fever death rate in Chicago from 1890 to 1892 averaged 12.5 per 10,000. After improving the water supply it fell with every step in improvement until last year it was only 1.9 per 10,000, a total reduction of 84.8 during the decade. The rate from this disease in Lawrence, Mass., for five years prior to 1893, was 12.7 per 10,000. After the establishment of sand filters, in September, 1893, the rate fell during the first twelve months to 5.2 per 10,000.

Munich was notorious for its excessive typhoid fever death rate, it being 29 per 10,000 in 1856. With the introduction of a pure water supply and improved sewer system it has fallen to less than 2 per 10,000. The experience of London, Berlin, Vienna, Albany and a host of other cities has been precisely the same.*

SEWAGE DISPOSAL AND RIVER POLLUTION.

When we remember that in 1896, 41 per cent. of our population lived in towns having public water supplies, and only 28.7 per cent. in sewered towns, we fear that the municipal authorities have failed to recognize the necessity that a system of public sewerage must go hand in hand with the public water supply, the neglect of which simply compels recourse to the various makeshifts for the collection and removal of excreta, and leads to soil pollution and all the other evils already referred to.

In view of the fact that self-purification of rivers is a slow and uncertain process, and that streams once polluted with excrementitious matter cannot be considered a safe water supply, it is high time for civilized communities to take steps toward removing the danger

to be found in rivers, which are the sewers and at the same time the sources of public water supplies.

We know, from statistics collected by the Marine-Hospital Service, that the towns and cities located on the banks of the Ohio, Potomac, Mississippi, Merrimac, Connecticut, Missouri, the Red, the Columbia and Wabash rivers show a marked prevalence of typhoid fever, confirming what has elsewhere been proved, that this disease, as also cholera, dysentery, and diarrhoeal diseases, can be carried from one town or city to another by means of water courses. There were probably no fewer than 35,000 deaths caused by typhoid fever alone throughout the United States last year and, based upon an estimated mortality of 10 per cent., it is within reason to assume a yearly prevalence of 350,000 cases of this disease. The average duration of a case of typhoid fever is not less than thirty days. If we calculate that an average of \$1 a day is expended for care, treatment and loss of work, and that the value of a human life is \$5,000, we have a total loss in the United States of \$185,500,000 per annum, from one of the so-called preventable diseases. Reduce the prevalence of this single disease one half, which has been accomplished in England, and the oft-recurring question: "How is it our fathers got along without these so-called modern improvements?" will be satisfactorily answered from an economic point of view.

One of the most pressing needs is an investigation into the pollution of water supplies when such pollution affects or threatens to affect the sanitary condition of the people of more than one State, because the individual States are powerless to protect themselves against the misdeeds of their neighbors. Mr. Bartholdi's bill for the appointment of a river pollution commission was defeated; yet that same Congress appropriated \$40,000 for the extermination of the gipsy moth. England enjoyed the benefit of such a commission as early as 1855, and, in order to prevent, remedy and remove the danger of polluted water supplies, adopted a comprehensive system for the disposal of sewage and water filtration, the fruits of which have already been referred to.

No community or individual has a right to pollute streams used for public water supplies any more than a man has to contaminate his neighbor's well. This principle is very well appreciated by some of the nations in Europe. Thus the inhabitants of a town in Belgium suffered from the effects of a river polluted by the French, and the French Government not only compelled the offending town to dispose of its sewage by irrigation, but also granted a subsidy for this purpose.

In the interest of public health it is to be hoped that every State in the Union will take steps toward the prevention of river pollution, except when towns are located close to the sea, and no lower towns are obliged to use the water for drinking purposes.

In 1878 the British Government appointed a committee to inquire into the several methods of sewage dis-

*In 25 cities using unfiltered water the average typhoid death rate is still 7.7 per 10,000; in 5 American cities supplied with water filtered by the American process, the rate is 5.5, against a rate of 1.1 per 10,000 in cities supplied with water filtered by the natural or English method. The average rate of 5 cities in Europe supplied with mountain springs or deep wells from unpolluted sources is only 0.7 per 10,000.

posal and concluded that it could be best and most cheaply disposed of by the process of land irrigation for agricultural purposes; but as this is not always practicable, other modes of dealing with sewage have been proposed.

It is a gratifying fact that within the past ten or twelve years, over one hundred communities in the United States have established plants for the disposal of sewage. The first attempt was made in 1872 at the State Insane Asylum, Augusta, Me., since which time seventy-eight plants for the disposal by irrigation, and fifteen by chemical treatment, have been established and over forty more projected.

PURE FOOD AND DRUG LEGISLATION.

The first movement toward securing comprehensive legislation against the adulteration of foods and drugs in this country was made in 1879. This is all the more surprising because Dr. Mann, in his *Medical Sketches of 1812*, remarks that "the bread on the Niagara was made of damaged flour, such as was either not nutritious or absolutely deleterious." It was believed also that the flour contained in some instances an earthy substance, and that this adulterating substance was plaster-of-paris. Again, during the civil war, so early as the winter of 1861-62, an extract of coffee furnished the troops in the vicinity of Alexandria produced nausea and vomiting, and subsequently a government contractor, for having practiced food adulteration, was sentenced to a protracted imprisonment.

Instances, therefore, were not wanting pointing to the necessity of such laws; nevertheless, it was not until 1881 that three States, New Jersey, New York, and Michigan, passed laws to prevent the adulteration of food and drugs. The law in New York commenced in the summer of 1882. At the close of the year, 286 samples of food and drugs had been submitted to the public analyst for examination, of which 194 had been reported on. Of 119 samples of food, 50 were found adulterated; while of 75 samples of drugs, 32 were adulterated.

Since 1883 quite a number of States have enacted similar laws, but I regret to say that in spite of the absolute necessity for national legislation, which has been agitated ever since 1892, so far every bill presented to Congress has failed to become a law, and food adulterated in one State can be taken to another and sold. It would lead me entirely too far even to touch upon all the frauds which are daily perpetrated. Some adulterations are harmful, others are not. I will simply refer to a very universal article of food, viz., milk. New York city obtains its milk supply from five States, and this amounted in 1896 to nearly 729,000 quarts a day. Analysis of the milk sold some years ago showed an average dilution with 33 per cent. of water. The State inspector found 12 per cent. of water added and 20 per cent. of cream removed, the fraud amounting to over \$10,000 a day. The results in St. Louis, Chicago, and

elsewhere were similar, and indicated the desirability of stringent laws to protect the pocket of the consumer, but when we remember the frightful infantile mortality, and the fact that the speaker has recently presented his conclusions, based upon 195 epidemics of typhoid fever, 99 of scarlet fever, and 36 of diphtheria, and that 52 of these outbreaks occurred in this country since 1882, we see at once that the milk traffic should be under strict sanitary control.*

LAWS REGULATING THE SALE OF DRUGS AND POISONS.

Forty-two States and Territories have enacted laws to regulate the sale of poisons, but a careful study shows that they should be amended, and greater restriction placed on the sale of poisons generally. A recent investigation by a committee of the Medical and Surgical Society into the extent of the opium and drug habit in the District of Columbia developed some interesting facts, and led to the conclusion that one class of subjects has developed the opium habit by the use of the milder preparation of opium and some of the various proprietary or secret remedies commonly employed as domestic remedies, such as paregoric, McMunn's elixir, chlorodyne, blackdrop, soothing syrup, diarrhoea mixtures, pain killers, etc. Those of another class have evidently acquired the habit by the constant use of prescriptions containing opium, or its preparations for the relief of pain, the individuals being at first quite unconscious of the enslaving nature of the drug. Still another class of persons belong to the moral degenerates of fast men and women who have acquired the habit by contact with opium habitués, including opium smokers, and through solicitation, invitation, and persuasion have fallen victims to the vice. Since the opium habit is often established by the unauthorized and indiscriminate renewal of prescriptions containing opiates, the New York Legislature very wisely enacted, in 1886, a law that no pharmacist should refill more than once prescriptions containing opium or morphine, or preparations of either, in which the dose of opium should exceed $\frac{1}{4}$ grain, or morphine $\frac{1}{20}$ th grain, except with the verbal or written order of a physician.

It is clearly the duty of the State to close opium dens and restrict the sale of poisons, and in regard to the sale of patent and proprietary medicines containing poisonous drugs, the contents should be expressed on the label and the word poison added.

PATENT AND PROPRIETARY MEDICINES.

By the term patent medicine, as properly employed in this country, England, and Europe generally, it must be understood that the composition is known, and can be seen, at the patent office. The proprietary medicine is a secret preparation protected by a trade mark in this

*The results achieved by the health officers of every large city, notably by Reynolds, of Chicago; Wende, of Buffalo, and Woodward, of Washington, in the reduction of infantile mortality, amounting in some instances to over 50 per cent., show the advantage of pure food legislation.

country, and hence preferred by the owner, but both are vaguely termed by the public patent medicines. Up to December 10, 1900, the United States Patent Office had issued patents on the following:* Disinfectants, 321; extracts, 250; hair dyes and tonics, 48; insecticides, 180; internal remedies, 376; plasters, 56; topical remedies, 371; veterinary, 78. Trade marks:† Drugs and chemicals, 319; medical compounds, 5,974, and increasing at the rate of about 250 a year.

The proprietary medicines are subject to the control of the State authorities, and, if containing alcohol in sufficient quantity to be intoxicants, are subject to internal revenue laws; but so far as my knowledge extends, little or nothing has been done in this country and in England to control the sale of secret remedies. Dr. G. Danford Thomas, coroner of London and Middlesex, before the International Congress of Hygiene, in 1891, very justly urged that all proprietary medicines should be under the patent laws, because the composition is at least disclosed; he would abolish licenses to sell them and confine the sale to chemists and druggists only. In these matters we could certainly profit by the example of the Japanese, Italian, French, and German laws. In the interest of public health the profession should demand adequate legislation; as it is now, hundreds of these proprietary preparations, the composition of which need not even be disclosed to the patent office, are advertised in medical journals.

INDUSTRIAL HYGIENE.

The relations of occupation to health and life were studied so early as 1700 by Ramazzini, an Italian physician, and since then numerous monographs have appeared. We know to-day that persons habitually engaged in hard work, especially in factories and indoors, present a higher mortality than persons more favorably situated, and that the character of occupations influences, to a great extent, not only the average expectation of life, but also the prevalence of certain diseases. We know, for example, that tuberculosis is much more frequent among persons engaged in dust-inhaling occupations, and that the sharp, angular particles of iron and stone dust are more liable to produce lesions of the respiratory mucosa than coal, flour, grain, and tobacco dust. We know, too, that certain establishments, like slaughter-houses, glue, soap, and candle factories, chemical factories, etc., are more or less productive of noxious and offensive gases, and that workers in lead, mercury, arsenic, phosphorus, poisonous dyes, etc., suffer especially from the injurious effects, and that other occupations, such as mining, railroading, and contact with moving machinery, involve special danger to life and limb.

For all these reasons the laboring classes need special protection, and in order to render this efficient, it must

*Information kindly furnished by Dr. J. B. Littlewood, of the Patent Office.

†Information collected from files of the U. S. Patent Office, by the author.

be provided for by the enactment and enforcement of suitable laws. In 1864, 1867, and 1870, England enacted the so-called factory laws. According to Miss S. S. Whittlesey's *Essay on Massachusetts Labor Legislation*, child labor, here as in England, was the first aspect to receive attention in legislation, as early as 1836. The first law as regards safety and sanitation was enacted in that State in 1877, since which time, from information kindly furnished by the Hon. Carroll D. Wright, of the United States Department of Labor, thirty-two States have enacted similar laws, including legislation requiring seats to be furnished saleswomen in stores and shops. Indeed, in some of the States the latter requirement is the only sanitary regulation. As a result of these laws, the majority of which were enacted during the last decade, commendable progress has been made in the way of ventilation, heating, lighting, removal of dust and injurious gases, means of escape in case of fire, and prevention of injuries by moving machinery.

It is quite true there are other factors which affect the health and longevity of wage-earners adversely. So, for instance, unsanitary dwellings, faulty nutrition—the results of badly prepared food and cold lunches—cannot fail to lower the power of resistance to disease, especially when the individual, in consequence of these very causes, has also become a victim of the alcohol habit.

SANITARY DWELLINGS FOR WAGE-EARNERS.

No field affords better opportunity for philanthropic work than the erection of sanitary homes for wage-earners at reasonable rentals, the encouragement of cookery schools, the establishment of sanitary lodgings, model eating-houses, and other betterments of industrial conditions.

The vital statistics of London show that the mortality in the improved dwellings for wage-earners is far below the general mortality of the city, the difference being specially marked in the infantile mortality; the general average during the five years ending December, 1890, was 153 per 1,000, while in the "George Peabody" and the "Metropolitan dwellings" it was only 136 and 121 respectively.*

*At a recent meeting of the American Social Science Association, held in Washington, April 18, 1901, Mr. J. H. Patterson, of Dayton, Ohio, read a paper on factory sanitation and described a large manufacturing plant of which he was the head, and their close adherence to the principles of hygiene and the uplifting of mankind. The interior of the factory is painted in cheerful colors, extra windows have been made to give light, forced ventilation to afford plenty of fresh air, and all dust and acid fumes are carried away by exhaust fans. Bath-rooms and well-furnished toilet-rooms are on all the floors. All seats have backs. Clean aprons are furnished by the company, and a dining-room where hot meals are served, and a course in domestic economy is conducted. The grounds around the factory, and the houses of the employees, are healthful and attractive. "We have demonstrated," said Mr. Patterson, "that this system pays the employee, the manufacturer, and the buyer; in the health of one, profit of the second, and the improved quality of the product purchased by the third." Bulletin No. 31, Department of Labor, November, 1900, contains an article on betterment of industrial conditions, showing what has elsewhere been accomplished, every effort being in the right direction, except that free medical attendance is being furnished by certain companies, involving a contract system with physicians, which ought never to gain a foothold on American soil, because it has proved a bane to the profession elsewhere.

When we consider the fact that over 70 per cent. of our population reside in rural districts, that the "bone and sinew" of these are engaged in agricultural pursuits, and that they do not enjoy the benefits of enforced sanitation by local health boards, we see at once the desirability of the family physician extending useful suggestions on healthful building sites and homes, disposal of house wastes, the importance of a pure water supply, wholesome and properly cooked food, etc. As it is now, the diet is faulty, especially the hot biscuits and greasy fried dishes, while wells and privies are often dangerous neighbors. The undue prevalence of typhoid fever in rural districts could be materially checked by disinfecting the stools with three times the volume of boiling water and the adoption of the earth closet system. This is all the more important since infection is often spread through the milk supply, and many of our urban population contract disease in the country during the summer months. While prompt disinfection of the excreta is the only rational method, we should also make an effort to get rid of the flies by prompt disposal of the horse manure in which they breed, the abandonment of open privies and surface pollution, and the removal of garbage and other fly-breeding matter.

SANITATION OF PRISONS.

Most commendable progress has been made in the construction and management of modern prisons. The mortality at the close of the last century, among prisoners in some of the French prisons, was 250 per 1,000; between 1840 and 1849 it was still 80.2 per 1,000, at St. Gallen, while to-day it is less than 30 per 1,000. Tuberculosis, typhoid fever, diarrhoea, croupous pneumonia, and mental disorders are the most prevalent diseases, but much will be done in future to reduce the excessive mortality by improved lighting, heating, ventilation, good food, bathing facilities, etc.

In some of the damp, dark, and gloomy prisons of Germany over 50 per cent. of all the deaths are from consumption. In the Mill-Bank prison of London, from 1825 to 1842, there were 175 deaths, of which no less than 75 were due to tuberculosis. Besides, 90 prisoners were set free on account of being hopelessly afflicted with pulmonary tuberculosis. In the Illinois State Prison, at Joliet, during the year 1895, 39 deaths were reported from consumption; in 1900 only 8 occurred. This decrease appears to be due directly to segregation of tuberculous subjects.

HOSPITALS, SANITARIA, AND DISPENSARIES.

Perhaps no country in the world can boast of better hospital facilities than our own. Indeed, many of our institutions are perfect in sanitary architecture and equipment. There are in the United States no less than 1,776 hospitals, including 35 special hospitals for consumptives; 308 sanitoria, 213 dispensaries, and over 8,000 mineral springs, of which 727 are health resorts.

Unfortunately, the liberality with which medical charities have been supplied has given rise to shameful abuses, and persons who would shrink from seeking charity in any other form have abused the privileges offered by hospitals and dispensaries.

Correction of Abuses.—In 1896, speaking of the city of Washington, no fewer than 21 per cent. of the population received free medical treatment; the medical association in 1897 adopted certain rules compelling the attending staff of hospitals and dispensaries to require evidence of dependency; as a result of this system there has been a gradual but positive decrease in the number of charity patients, amounting to over 9,000 last year. It is the simplest, most just and effective remedy for the correction of this evil.

SCHOOL HYGIENE.

During the year ending June 30, 1900, there were 15,341,220 children enrolled in the common schools of our country. When we consider that the mental and physical vigor of a nation depends largely on the environments of childhood and youth, it seems strange that up to within forty years little or no attention should have been paid to the hygiene of schools. The occurrence of so-called school diseases is not surprising when we reflect that children, on beginning school, enter upon a new life and environment. Up to this time they have been allowed to run and play in the open air, exercise the body and senses, without restraint, but now without a period of transition they are obliged to remain for several hours a day in close and sometimes unsanitary school rooms, taxing their minds and straining their eyes for near objects. Experience teaches and statistics confirm the conclusion, that quite a number of children suffer from certain physical defects and diseases, which, because rarely observed before the school period, may be justly attributed to the school environments. Among the most common of these affections are myopia, lateral curvature of the spine, dyspepsia, anæmia, muscular debility, headache, and nose-bleed, nervous affections and tuberculosis. Ware, of our own country, so early as 1812, called attention to the fact that myopia was most frequently developed in the school room, and during the past forty years we have been enlightened as to the cause of this and other defects, and many excellent monographs have been written on the construction of school buildings, arrangement of recitation-rooms, as regards light, ventilation, adjustable seats and desks, proper type for textbooks, and more rational methods of mental and physical training. This, together with a commendable zeal on the part of the authorities to correct existing evils, has resulted in many reforms, the fruits of which are already apparent in a decrease of the diseases referred to.

Medical Inspection.—I cannot enter into details concerning the prevention of the spread of infectious diseases among school children, but desire to emphasize the necessity of medical inspectors, whose duty it should be to

visit the schools, examine pupils, and give such directions as will reduce the dangers of spreading contagious diseases to a minimum; they should also make sanitary inspection of the buildings and present such recommendations as are necessary in the interest of the health of both the pupils and teachers, and as the physicians were perhaps the first to recognize the fact that "the system of education should be made to fit the child, not the child the system," the teachers may derive much aid from such consultations; among the cities that have inaugurated such inspections since 1894 are Boston, New York, Brooklyn, Chicago, Milwaukee, Louisville, St. Louis, Philadelphia, Jersey City, Brookline, Mass., Buffalo, Minneapolis, and Salt Lake City, and they have proved of inestimable value.

SMALLPOX AND COMPULSORY VACCINATION.

In this connection attention is invited to the undue prevalence of smallpox in the United States; the total number of cases reported to the U. S. Marine-Hospital Service during the past fall and winter, up to March 29th, was 11,964, as compared with 7,279 cases for the corresponding period of the preceding year, and it is doubtless due to neglect in vaccination. Dr. Abbott estimates the vaccinated portion of the inhabitants of the United States at not far from 90 per cent., and the re-vaccinated portion at probably 50 per cent. With the introduction of glycerinated animal lymph every vestige of prejudice against vaccination should cease, and compulsory laws should be enacted in every State, so that smallpox here, as in the German army, may become practically unknown. While quite a number of States have enacted laws requiring that unvaccinated children shall not be admitted to the public schools, it is believed that these laws are not rigidly enforced.

VENEREAL DISEASES.

A careful perusal of Dr. Prince A. Morrow's article on The Prophylaxis of Venereal Diseases (*Philadelphia Medical Journal*, April 6, 1901) should stimulate our efforts in the prevention of diseases which affect, not only the offender, but innocent wives, the offspring, and not infrequently even the medical attendant. According to Fournier, one seventh of the population of Paris is syphilitic, and Morrow, from statistics gathered in New York, believes it is quite possible that Fournier's figures, with some modification, may apply to New York. Neisser holds that gonorrhœa is, with the exception of perhaps measles, the most widespread of all diseases. Other German authorities have computed that fully three quarters of the adult male population and one sixth or more of the adult females have contracted gonorrhœa; that 80 per cent. of all deaths from disease of the uterus and its adnexa are of gonorrhœal origin, while blennorrhœa neonatorum contributes a contingent to our asylums for the blind, estimated at from 10 to 20 per cent.—from 40 to 60 per cent. before the Credé method was instituted—not

to mention the destructive effects on the procreative functions. Dr. S. M. Burnett, of Georgetown University, believes that 15,000 of the 50,000 blind persons in the United States lost their sight from this cause, which according to his calculation involves a financial loss to the commonwealth of seven and one half millions annually.

The measures which have been proposed for the control of the social evil and the prevention of its consequences are numerous enough, but not so easy of practical application. On the whole, I believe the remedy lies in public education, and the task as usual falls on the medical profession, especially the trusted family physician. Public lecturers on the purity of man commit a serious mistake, however, when they picture the consequences of the social evil, without offering a suitable remedy. We should make a strong plea in favor of continence, and tell our young men that, while the sexual passion is very strong, it can be accelerated or delayed, excited or lowered by the influence of the will. We should assure them that by the cultivation of pure thought, removal of temptation, normal, mental, and vigorous physical exercise, continence may not only become possible, but easy. And we can hardly go astray if we follow Dr. Parkes in advising a pure young man to make his home, after the age of twenty-one, and thus secure himself both from the temptations and expenses of bachelorhood.

THE MANAGEMENT AND CONTROL OF INFECTIOUS DISEASES.

It is the field of infectious diseases where preventive medicine has and doubtless will continue to achieve its greatest triumphs, and there is ample room, when we consider that during the census year of 1890 there were not less than 102,199 deaths from consumption, 74,496 from pneumonia, 74,711 from diarrhœal diseases, 41,677 from diphtheria, and 25,058 from typhoid fever. In spite of centuries of groping after facts, we knew nothing of the real nature of infectious diseases until the middle of the present century, and even twenty-five years ago the text-books still discussed the subject of miasmata and contagia, whose nature had never been demonstrated to our senses. With improved microscopic lenses and the development of bacteriology, more especially the discovery of the anthrax bacillus by Davaine, Pollender and Brauell (1849-1855), scientific medicine had its birth, and to-day we know that such diseases as tuberculosis, glanders, leprosy, cholera, erysipelas, wound and puerperal infections, gonorrhœa, pneumonia, cerebrospinal meningitis, typhoid fever, diphtheria, malaria, influenza, dysentery, bubonic plague, and possibly carcinoma, are caused by living organisms, capable of reproduction within and without the body, and this is a strong argument in favor of the microbic nature of other infectious diseases, in which the specific organism has not yet been isolated.

The eradication of preventable diseases is the highest aim of scientific medicine to-day. The public should

be made familiar with the nature and causes of infectious diseases, and be taught that many are a source of danger, against which it is entitled to be warned by proper notification through the health officer. This notification should be made compulsory in cholera, yellow fever, smallpox, chicken-pox, typhus and typhoid fever, diphtheria and membranous croup, scarlet fever, tuberculosis, cerebrospinal meningitis, leprosy, glanders, bubonic plague, whooping-cough and measles. And let me say that a prompt and correct diagnosis is the first and most important step in preventive measures. The health department should have competent medical inspectors and a clinical laboratory for the verification of the diagnosis, and have the power in certain of these diseases to display warning signs, enforce isolation and disinfection, and to take such other steps in the way of immunizing agents as may be deemed necessary to limit their spread.

Isolation, to be effective, should extend to all persons who have come in intimate contact with the patient, but this is rarely enforced except in smallpox, in the case of the attending physician, and the wage-earners of the family, but it is clearly their duty to take special precautions in the way of clothing and personal disinfection. Matters of this kind ought never to be left to the discretion of the family, or the attending physicians, for even members of the profession often entertain widely opposing opinions on the subject of quarantine and disinfection, but the principles which ought to be carried out, apart from being a matter of conscience, should be accepted in a practical sense and embodied in effective laws.

Disinfection.—Scientific disinfection had its inception with the labors of Koch and Sternberg some twenty years ago. Although, as we have seen, certain physical and chemical agents were used empirically for ages, now we know from laboratory experiments that they are effective, because they destroy the vitality of the germs. We also know that, in most of the contagious diseases, the infective matter is given off by the patient chiefly through the secretions and excretions, and it is evident that disinfection to be of value must be directed to these and all the media with which the patient has come in contact.

“IF CERTAIN DISEASES ARE PREVENTABLE, WHY ARE THEY NOT PREVENTED?”

My answer is, that while every scientific physician familiar with biologic research knows full well that if the methods of prevention recommended by sanitarians, including the prompt disinfection of the dejecta of every typhoid fever patient, and of the expectoration and excretions of diphtheria and tuberculosis patients, for example, were adopted, these diseases would be reduced to a minimum and probably eradicated in the course of a few years. The facts are, these recommendations have not been generally adopted, because the knowledge

gained by experimental medicine is not sufficiently diffused. Nor are we responsible for the fact that so many of our States still permit every charlatan to practise one of the most difficult and responsible of all professions without a uniform and rigid system of examination. However, we owe it to ourselves and to humanity to take positive steps in behalf of higher medical education and laws regulating the practice of medicine.* So long as we permit the existence of irregular and incompetent practitioners, so long will the public be deceived and shall we be obliged to compete with incompetent men, and so long as we tolerate the exponents of so-called “Christian Science,” osteopathy, and other quacks, infectious diseases will be spread as the result of ignorance and neglect. A strong organization, such as is proposed for the American Medical Association, and the various State medical societies, will speedily accomplish this and other reforms.

FORECAST OF THE RESULT OF THE CENSUS WORK UPON THE MORTALITY STATISTICS.

Notwithstanding these and other disadvantages in the way of defective sanitary legislation, the American medical profession has reason to be proud of its work in the century's progress of hygiene and preventive medicine. It may be truly said that every hospital or other medical charity owes its foundation and success to the activities of the medical profession. Nay, every law inscribed on the statute books, in the interest of public health in this and other countries, is the work of our noble profession. Acting upon the lofty principle that the education and betterment of the people in sanitation is not less humane than the healing of the sick, the American medical profession has filled the measures of its philanthropy by advocating laws to “regulate the health and physical well-being of communities,” and thereby to lessen its own income, but the results obtained during the last ten years are sufficient recompense. By the courtesy of Mr. William A. King, Chief Statistician of the United States Census Bureau, I am enabled to give you a forecast of the result of the work upon the mortality statistics at the close of the century:

The mortality returns for the twelfth census, which relate to the year beginning June 1, 1899, and ending May 31, 1900, have not yet been tabulated in full, but sufficient progress has been made to permit a comparison

*During the year 1900 there were 119 regular medical schools in this country, with 1,079 female and 21,673 male students; of these 22,752 students, 2,327, or about 10 per cent., had degrees of A. B. or B. L. Number of graduates last year, 4,720. The homeopathic schools had 1,584 male and 325 female students, and the eclectic 500 male and 52 female students. The number of registered physicians in the United States in 1900 shows an average for the whole of about 1 to 636 inhabitants. In 31 States and Territories, according to D. McIntyre, an examination is required; in 9, certain diplomas are accepted, all others must be examined; in 5, only a diploma is required; and in 5, the laws practically impose no restriction. In 1900 there were 150 national and State medical societies, 1,097 county and local medical societies, and 282 medical journals, of which 28 were exclusively devoted to hygiene and public health.

of the preliminary results with the figures for 1890 for a portion of the country.

Considering these results for these States in which the returns were secured from registration records in both 1890 and 1900, there appears to have been an absolute decrease in the general death rate of about 1.5 per 1,000 of population. This decrease seems to be most marked in the rates due to scarlet fever, whooping-cough, diphtheria and croup (combined), typhoid fever, malarial fever, consumption, diarrhoeal diseases, and diseases of the nervous system, the decrease in the mortality from diphtheria and croup amounting to more than 50 per cent. On the other hand, the rates due to carcinoma and tumor (combined), Bright's disease, heart disease and dropsy (combined), and pneumonia are apparently greater than in 1890, the increase being most marked in case of Bright's disease, carcinoma and tumor, and pneumonia.

The death rate by age periods in the registration States has not yet been computed as the population figures are not yet available, but the effect of the decrease in the rates due to the causes specified is shown by a decrease in the proportion of deaths occurring at each period up to 30 years.

The results in the decreased rate of diphtheria, croup, scarlet fever, typhoid fever, whooping-cough, consumption, malarial fever and diarrhoeal diseases are the direct outcome of preventive medicine and are as gratifying as they are striking. We note with regret the increased rate in Bright's disease, heart disease, dropsy and pneumonia, and may well pause to inquire whether our ever-increasing "national drink bill," averaging 17.68 gallons *per capita*, may not be a factor in the development of these diseases, especially since there is reason to believe that the habitual and immoderate use of alcohol, apart from increasing the connective tissue and causing cirrhosis, also produces fatty degeneration, especially of the heart, liver, and arterial coats, probably because it promotes the conversion of albuminoids into fats.

Without wishing to underrate the brilliant achievements in surgery of the brain, stomach, intestines, liver, gall-bladder and other abdominal organs, and even wounds of the human heart which have been successfully sutured in four of the nine cases reported, what, after all, are the ultimate benefits compared with the results obtained by improved methods in sanitation?

Since our knowledge of the nature of infectious diseases has been more and more defined, scientific methods for their prevention have been applied. We have learned, too, that in addition to the germ there must be a suitable soil for its proliferation and that sanitation will not only destroy the environments for its development without the body, but also place the system in the best possible condition to resist in its toxic action.

The application of this knowledge has saved millions of lives besides an incalculable amount of human suffering and distress, not to mention the economic aspect

of the question. When we remember all this and the fact that Jenner's discovery at the close of the last century, of a fundamental and practical method of producing artificial immunity, has been far eclipsed in the last twenty years, and that we possess to-day not only curative but also protective sera for diphtheria, erysipelas, tetanus, plague and possibly cholera, tuberculosis, typhoid fever, pneumonia, and a number of other immunizing agents for diseases of man and lower animals, we have reason to believe that the solution of the problem of immunity is only a question of time, and we may indeed expect great possibilities in our battle against infectious diseases.

To the solution of this problem, the labors of Salmon and Smith, Sternberg, Welch, Osler, Councilman, Reed and other Americans engaged in experimental medicine have contributed their full share. Progress has crowned our past, we will not retrograde. Let our conduct raise no blush on the cheek of posterity. Let us hand in hand with heart and mind join in promoting the welfare of American medicine, until she has reached the proudest pinnacle in the world of science, until she has become the fountain-head of knowledge for the benefit of mankind. Then when at last we are called upon to pass through the portals beyond, Minerva Medica, in her sweeping robes of state, will proudly but reverently present us to the Supreme Healer of the Universe as types of the true physician.*

Births, Marriages, and Deaths.

Married.

DODGE—CLEGHORN.—In Chicago, on Tuesday, June 4th, Dr. Austin C. Dodge, of New York, and Miss Mary A. Cleghorn.

FIELDER—IRWIN.—At "Fair Lawn," Greenbush Heights, N. Y., on Saturday, June 1st, Dr. Frank Sidney Fielder, of New York, and Miss Martha Teller Irwin.

PEASE—SPEAR.—In New York, on Saturday, June 1st, Dr. Charles G. Pease and Miss Mary Leonora Spear.

SAPPINGTON—JACOB.—In Belair, Pennsylvania, on Tuesday, June 4th, Dr. John Sappington and Miss Rosa Seldon Jacob.

WAINWRIGHT—HART.—In Englewood, N. J., on Friday, May 31st, Dr. G. Mayhew Wainwright and Miss Jessie Bell Hart.

Died.

BENSON.—In New York, on Saturday, June 1st, Dr. Samuel L. Benson, in the sixty-fourth year of his age.

COMFORT.—In New York, on Wednesday, May 29th, Dr. John E. Comfort, in the sixty-fourth year of his age.

FEENY.—In Stapleton, N. Y., on Friday, May 31st, Dr. John L. Feeny, in the fifty-sixth year of his age.

HOYT.—In Kansas City, Missouri, on Tuesday, May 21st, Dr. Frank Crampton Hoyt, of Mount Pleasant, Iowa, in the forty-third year of his age.

MERGLER.—In Los Angeles, California, on Saturday, May 18th, Dr. Marie J. Mergler, of Chicago.

STOCKDELL.—In Petersburg, Virginia, on Thursday, May 23d, Dr. Hugh Stockdell, in the sixty-sixth year of his age.

SUMNER.—In Boston, on Saturday, May 25th, Dr. Allen M. Sumner, in the fifty-seventh year of his age.

WITHAM.—In Lebanon, Ohio, on Friday, May 24th, Dr. W. L. Witham.

*In the preparation of this address I have been greatly aided by the library of the surgeon-general's office, the historical monographs on hygiene, by Professor Kinkelburg, of Bonn, now deceased, and Dr. S. W. Abbott, of our own country. I am also greatly indebted to Dr. W. T. Harris, the commissioner of education, and Dr. A. E. Miller, of his bureau. Other acknowledgments have been made in the text and are gratefully renewed.

THE AMERICAN MEDICAL ASSOCIATION

FIFTY-SECOND ANNUAL MEETING, ST. PAUL, MINN., JUNE 4, 5, 6, and 7, 1901.

THE PLACE OF MEETING.

SITUATED as it is upon three plateaus of different levels, St. Paul is admirably located from a scenic standpoint. Along the lowest of these levels, just above the river bank, lie the railway stations, the manufacturing industries and the wholesale mercantile houses. On the second plateau are the retail establishments and some residences, while on the highest level of all with a

part daily, besides being at the head of navigation on the Mississippi River. As a place of residence St. Paul is most attractive, and its municipal authorities have done much to add to its natural advantages by making numerous parks, and by the exercise of great care as regards matters of sanitation. The water supply is excellent and is sufficient to meet the needs of the city for many years to come. The city is well supplied with hospitals, one of

BIRD'S-EYE VIEW OF ST. PAUL FROM SUMMIT AVENUE.

commanding outlook stands the most beautiful part of the city, that devoted exclusively to the residences.

The first building on the present site of this city was erected in 1841 by the French priest and in 1850 the population amounted only to 1,294. Within the next decade this number had grown to over 10,000 and the city now has some 150,000 inhabitants. St. Paul has been the capital of Minnesota since territorial organization. It has many large manufacturing establishments in various lines and is probably the most important distributing centre in the Northwest, having some twenty-four lines of railway, upon which 300 passenger trains arrive and de-

part daily, and the Medical Department of the State University, which is in Minneapolis, just without the city limits of St. Paul, is an institution of high standing. Minneapolis, which adjoins St. Paul, is the largest flouring mill centre in the world and is an excellent representative of the progressive cities of the Western portion of the United States.

The physicians of both cities joined in preparing an attractive programme of entertainment for physicians attending the meeting, and left nothing undone that it was possible to do to make the stay of the visitors agreeable.

THE PRELIMINARY MEETINGS.

TO appreciate the atmosphere in which the fifty-second annual meeting of the American Medical Association opened, one must take some note of the quality of men brought together in St. Paul during the few days preceding the meeting, and of the nature of their work, in connection with certain other organizations which, from considerations of convenience, meet in the same city and shortly before the larger association's meeting.

Prominent among these is the Association of Military Surgeons of the United States, which held its tenth annual meeting in the State Capitol on Thursday, Friday, and Saturday, May 30th and 31st and June 1st, under the presidency of Brigadier-General Alexander J. Stone, of St. Paul, surgeon-general of the National Guard of the State of Minnesota. The meeting was rather a small one, and the programme was meagre, although the papers presented were of a high order of interest. This state of things was fully recognized—indeed, the tendency to it had been recognized at the preceding meeting, at which a committee was appointed to consider and report upon means for its correction connected with the mode of publication of the proceedings.

Heretofore the association has issued an annual volume of *Transactions*. Necessarily its appearance has been tardy, and this, of course, has been unsatisfactory to some of the contributors of papers, although they seem to have been at liberty to publish their contributions in medical journals of their own selection in advance of the appearance of the volume. The committee's report, presented at this meeting, favored the tentative issue of the proceedings in monthly parts. The report was received and accepted, but definite action providing for carrying the committee's recommendations into effect does not

appear to have been taken. There are those who think that the plan of holding the annual meeting at a time so close to that of the meeting of the American Medical Association, and in the same city, tends to defeat the very object in view. Attendance at both meetings, these gentlemen argue, involves for many of the members an absence from home of from ten days to a fortnight, and such a long absence is convenient for only very few of the members. Possibly, it is thought, there is more in these facts to account for the small meetings and the paucity of papers than in any diminution of enthusiasm consequent on tardy publication of the proceedings.

But, if this year's meeting was small, it has done what the most gigantic gathering could not have done more convincingly—protested in no uncertain terms against the abolition of the army canteen. Sympathy with this protest is manifested in all professional quarters, and it will doubtless meet with substantial support at the hands of numerous other medical organizations, including the American Medical Association itself.

The American Academy of Medicine is another organization that regularly holds its annual meeting immediately before that of the American Medical Association. It stands, as everybody in the profession knows, for continual ad-

vance in education, general as well as professional. It has stood well to its guns this year on the educational question, and, in addition, has contributed to the ultimate solution of the vexed question of inter-State reciprocity in the matter of the license to practise, but has had the misfortune to figure in the lay press as being diametrically opposed to the very objects it is seeking to promote.

Among other meetings held in St. Paul during the few days preceding that of the American Medical Association were those of the Association of Medical Colleges

JOHN A. WYETH, M. D.,
OF NEW YORK,
Newly Elected President of the American Medical Association.

of the United States, the Minnesota State Medical Society (a *pro-forma* meeting, but one at which an excellent presidential address was delivered by Dr. Davis), the National Association of Life Insurance Examiners, the National Convention of State Medical Examiners and Licensing Boards, and the Association of American Medical Editors; also, during the meeting, that of the American Proctological Society.

With all these meetings to distract the attention of the men who arrived early, to say nothing of the casual discussions held informally in hotel lobbies and other

five feet square on the fourth floor of the Ryan Building, with numerous large windows on two opposite sides. The specimens were displayed to the greatest advantage. As was to be expected, most of them came from points not far distant from St. Paul. Among those that seem worthy of special mention are the following:

From the Army Medical Museum, Washington, under the direction of Surgeon-General George M. Sternberg, Colonel Calvin De Witt, and Captain A. E. Bradley, Röntgen pictures of gunshot fractures sustained during the war with Spain and in the suppression of the Filipino

places of chance meeting concerning the proposed scheme of reorganization, the report of the nominating committee, and the choice of the next place of meeting, many a man has found evident relief in examining the Pathological Exhibit, even at a stage when it was still little more than nascent. The exhibit was under the direction of a committee consisting of Dr. Frank B. Wynn, of Indianapolis (chairman); Dr. A. P. Ohlmacher, of Gallipolis, Ohio, and Dr. H. Summa, of St. Louis, who are entitled to great credit for getting together so large and varied a display. The association, for its part, provided an ample and well-lighted room for the purpose, a room seventy-

rebellion, specimens of fractures from the civil war, specimens showing the lesions of typhoid fever and those of dysentery, casts of ancient Peruvian skulls, showing signs of prehistoric trephining, and a series of dental specimens.

From the Bureau of Animal Industry, Washington, under the direction of Dr. D. E. Salmon, specimens of tuberculous disease in the lower animals.

From the Cincinnati Academy of Medicine, under the direction of Dr. Horace J. Whitacre, a collection strong in prostatic and renal specimens.

From the Indiana State Medical Society, under the

ST. JOSEPH'S HOSPITAL, ST. PAUL.

direction of Dr. Frank B. Wynn, a hundred miscellaneous specimens, many of them of unusual interest.

From the Illinois State Medical Society, under the direction of Dr. Maximilian Herzog, about thirty specimens, mostly gynecological.

From the Kansas State Medical Society, under the direction of Dr. G. A. Boyd, a collection of about thirty-five specimens, together with various species of malaria-bearing mosquitoes.

From the Wisconsin State Medical Society, under the direction of Dr. Gustave A. Kletzsch, a series of specimens illustrating causes of sudden death. Prominent in this exhibit was a collection of gross specimens of various diseases of the eye, embedded in glycerin jelly, prepared by Dr. H. V. Würdemann.

From the Chicago Polyclinic, under the direction of Dr. Maximilian Herzog, a collection of miscellaneous specimens.

From the College of Physicians and Surgeons, Chicago, under the direction of Dr. W. A. Evans and Dr. A. Gehrman, a miscellaneous collection of gross specimens, also a series of bacteriological cultures bearing on sanitary work.

From McGill University, Montreal, under the direction of Dr. J. George Adami, two series of specimens,

one illustrative of cerebral aneurysms and the other of tuberculous disease.

From the Medico-chirurgical College, Philadelphia, under the direction of Dr. Joseph McFarland, a series of microscopical specimens showing the structure of the various forms of tumor of the breast.

From the Northwestern University Medical School, Chicago, under the direction of Dr. G. Fütterer and Dr. F. Robert Zeit, about a hundred specimens of tumors, several of them showing the relation of the scar of a gastric ulcer to the development of carcinoma.

From the Rush Medical College, Chicago, under the direction of Dr. Ludwig, a large collection of miscellaneous specimens.

From the State University of Minnesota, Minneapolis, under the direction of Dr. F. F. Westbrook, Dr. L. B. Wilson, and Dr. S. M. White, a large number of miscellaneous specimens, a series of most ingeniously colored wax casts showing the cutaneous lesions of small-pox, etc., and a series of culture tubes shown on a unique plan.

From Hamlin University, Minneapolis, under the direction of Dr. J. F. Corbett, a large series of bony preparations showing various pathological conditions.

From the Central Indiana Hospital for the Insane, under the direction of Dr. George F. Edenharter and Dr.

ST. ANTHONY FALLS, MINNEAPOLIS.

White, miscellaneous gross specimens illustrative of psychic pathology and a series of photographs of the insane.

From the Iowa State Hospital for the Insane, under the direction of Dr. Albert M. Barrett, a collection of miscellaneous psychiatric specimens.

From the Government Hospital for the Insane, Washington, under the direction of Dr. A. B. Richardson and Dr. J. W. Blackburn, a miscellaneous collection of psychiatric specimens.

From the Lakeside Hospital, Cleveland, under the direction of Dr. W. T. Howard, Jr., miscellaneous specimens.

From St. Luke's Hospital, Richmond, Va., under the direction of Dr. Stuart McGuire, a series of urethral calculi.

From the St. Peter State Hospital for the Insane, Minnesota, under the direction of Dr. H. D. Valin, a collection of neurological specimens.

From Dr. Frank Hugh Montgomery and Dr. James Nevins Hyde, Chicago, photographs of cases of blastomycetic dermatitis.

From Dr. Emil Amberg, Detroit, a large series of

bony specimens illustrative of ossicular, mastoid, and other aural affections.

The section dinners were held on Tuesday evening, those of the Section in Surgery and Anatomy, the Section in Obstetrics and Diseases of Women, and the Section in Cutaneous Medicine and Surgery at the Hotel Ryan; those of the Section in Practice of Medicine, the Section in Materia Medica, Pharmacy, and Therapeutics, the Section in Physiology and Dietetics, the Section in Hygiene and Sanitary Science, the Section in Pathology and Bacteriology at the Merchants' Hotel; that of the Section in Nervous and Mental Diseases at the Town and Country Club; those of the Section in Ophthalmology and the Section in Laryngology and Otology at the Minnesota Club; and those of the Section in Diseases of Children and the Section in Stomatology at the Windsor Hotel. On Thursday evening a reception and ball, provided for by the physicians of Minneapolis, took place in the armory and on the campus of the University of Minnesota. After the meeting there was an excursion to the Yellowstone Park. The members of the Minnesota State Medical Society, those of the Ramsey County Medical Society, and the physicians in general of

ST. PAUL CITY AND COUNTY HOSPITAL.

the twin cities of St. Paul and Minneapolis showed the greatest hospitality to their professional brethren from other parts of the country, and doubtless it was a confident expectation of this hospitality that called together such a host, for this was one of the largest meetings in the history of the association.

Perhaps the most notable feature of the meeting was the admirable rhetoric of the president's address. Rarely has the presidential chair been occupied by a man so well qualified as Dr. Reed to recount the real needs of the profession in the various States, and never has such a man's address called forth heartier applause. It may well be believed that the address went far in preparing the way for the committee's ready acceptance of the scheme for reorganization which has been outlined in the *Journal*.

The opening prayer, by Bishop H. B. Whipple, was followed by a brief address of welcome by the Hon. R. A. Smith, mayor of St. Paul, who made the statement that the city was the healthiest in the world. The people of St. Paul, he said, enjoyed the double blessing of long life and small doctors' bills. He attributed the low mortality to the natural advantages of the city as regarded location, etc., and to the great advances made in recent years in hygiene and medicine.

The address of the president was delivered by Dr. C. A. L. Reed, of Cincinnati. (See page 969.)

Presentation of a Portrait of Dr. N. S. Davis.—Dr. J. Rawson Pennington, of Chicago, presented to the association a fine portrait of Dr. N. S. Davis, of Chicago, the founder of the American Medical Association, its president in 1865, and its most constant attendant and faithful guide. Among many other honors conferred upon Dr. Davis during his professional career of sixty-five years had been the office of president of the Ninth International Medical Congress. Although eighty-five years

MEDICAL BUILDING, STATE UNIVERSITY, MINNEAPOLIS.

THE PROCEEDINGS OF THE FIFTY-SECOND ANNUAL MEETING.

THE first general session was held in the Metropolitan Opera House on Tuesday, June 4, 1901.

The meeting was called to order at 10.20 A. M. by Dr. John F. Fulton, of St. Paul, the chairman of the committee of arrangements.

of age, he was still able to devote from five to six hours daily to his patients, and to attend promptly to all the duties of good citizenship.

The portrait of Dr. Davis was accepted with the unanimous thanks of the association, and a motion was made and carried that a committee of three be appointed by the president for the purpose of securing, if possible, the portraits of other ex-presidents of the association.

The Report of the Treasurer.—Dr. T. J. Happel, of

DR. GEORGE H. SIMMONS,
Secretary of the American Medical Association.

Tennessee, a member of the board of trustees, to whom the report of the treasurer was made, stated that on June 1, 1901, the assets of the association were \$45,254. Adding to this the value of the plant of the association, swelled the total assets to \$66,000.

Saratoga, N. Y., was selected as the next place of meeting and the following officers were elected: President, Dr. John A. Wyeth, of New York; first vice-president, Dr. Alonzo Garcelon, of Maine; second vice-president, Dr. A. J. Stone, of Minnesota; third vice-president, Dr. A. F. Jonas, of Nebraska; fourth vice-president, Dr. James A. Dibrell, of Arkansas; treasurer, Dr. Henry P. Newman, of Illinois; secretary, Dr. George H. Simmons, of Illinois; board of trustees whose terms expire 1904, Dr. T. J. Happell, of Tennessee; Dr. W. W. Grant, of Colorado; Dr. John F. Fulton, of Minnesota; judicial council, Dr. George Cook, of New Hampshire; Dr. H. H. Grant, of Kentucky; Dr. John B. Murphy, of Illinois; Dr. Philip Marvel, of New Jersey; Dr. Louis H. Taylor, of Pennsylvania; Dr. John L. Dawson, of South Carolina; Dr. N. Fred Essig, of Washington; orator on surgery, Dr. Harry Sherman, of California; orator on medicine, Dr. Frank Billings, of Illinois; orator on State medicine, Dr. J. M. Emmert, of Iowa; chairman of the committee of arrangements, Dr. G. F. Comstock.

(To be continued.)

Section in Laryngology and Otology.

The Chairman's Address, by Dr. John N. Mackenzie, of Baltimore, was devoted to a defect in all medical schools, the lack of proper instruction in the study of diseases of the air-passages in the head and consequently

the ignorance as to the use of instruments. He took the broad ground of the benefits resulting to the public and obviously to the credit of the medical profession.

The Treatment of Laryngitis.—This was the title of a paper read by Dr. O. T. Freer, of Chicago. He recommended both local and general treatment. The local treatment was best carried out by the use of sprays; every part could be reached. Powders were not so satisfactory, and the probe was dangerous, as it was injurious to the already inflamed tissue. He also desired to emphasize the infectious character of all forms of acute laryngitis. There was an infected mucous membrane, a congested surface covered with leucocytes. All cases could not be treated with astringents; where there was great œdema, it became necessary to use the knife. The speaker passed rapidly over the condition of ozæna. When there was a new formation of connective tissue, with nodular formations or folds, early scarification was recommended. The chronically swollen cords were best treated by many small longitudinal incisions. Ichthyol was very useful in contracting the tissues. The difficulty in throwing the spray below the vocal cords had been relieved by the use of a long tube, which reached to the cords.

Dr. Ingals, of Chicago, had found deep inhalation after the use of the spray of benefit, the fluid being drawn down below the cords.

Dr. Freer said that, unless cocaine was previously used, the inhalation in many cases produced a marked spasm of the glottis.

Œdematous Laryngitis was the subject of a paper by Dr. Joseph S. Gibb, of Philadelphia. He described true

DR. JOHN N. MACKENZIE,
Chairman of the Section in Laryngology and Otology.

œdematous laryngitis as an inflammation of a mucous membrane, attended by serous transudation into the sub-mucous tissues. Much confusion had arisen from the

multiplicity of names, which might be obviated by drawing a sharp line between simple œdema without inflammation and that in which inflammation of the mucous surfaces was an active feature. Much of the confusion had arisen in attempting to classify all œdema cases under one head. The reader cited four cases. As to the ætiology of idiopathic œdema, there were several types of cases: Those in which there was no true inflam-

two years. A week ago the reader split the larynx between the cords, removed the papilloma, and sewed up the larynx.

Section in Materia Medica, Pharmacy, and Therapeutics.

Experimental Work in Intra-organic and Venous Injections and Blood Extracts in the Cure of Acute Organic Diseases.—This communication, by Dr. W. Byron Coakley, of Chicago, dwelt principally upon the use of sodium chloride, and especially normal salt solution, as a cardiovascular stimulant. The author maintained that it was entirely innocuous, even when injected into organs like the lungs, the spleen, the kidney, or the liver. If injected slowly and with a delicate trocar or needle, it would not produce hæmatoma. He alleged great value for subcutaneous intravenous or intra-organic injections for relieving pain and prolonging life. The normal salt solution was a powerful stimulant to a failing heart. After bleeding a dog until the heart had almost ceased to beat, the injection of a few centimetres of saturated salt solution into the pericardium restored the heart's action. He also maintained that it retarded carbon dioxide narcosis by causing absorption of the gas.

Neglected but Valuable Therapeutic Measures was the title of a paper by Dr. George F. Butler, of Chicago. Bloodletting, which had been discontinued in deference to popular prejudice, was now known to be of great therapeutic value. As a result of a better knowledge of its physiological effects, it had resumed its place in therapy. When performed for removing toxic agents and diluting the serum, its place could be taken in many cases by the modern injection of normal salt solution, but there were other cases in which the reduction of the volume of blood by venesection was indispensable to successful treatment. Counter-irritation, on account of popular prejudice, had also been almost abandoned, yet it was of great service in relieving pain and restoring healthy action. Surgical operations were often of service, irrespective of the location or indications for operation. Insane persons showed improvement, or recovered, after fracture of bones or similar injuries. He also spoke in support of hydrotherapy, massage, and suggestive therapeutics. He said that complex prescriptions were of greater value than single remedies, and were not "shotgun prescriptions" if scientifically composed to meet special indications. In conclusion, he advocated physical culture and especially outdoor exercise.

The Therapeutical Indications Presented by the Conditions of the Blood in Disease.—In a paper thus entitled, Dr. O. T. Osborne, of New Haven, protested against the treatment of disease as an abstraction and the too scientific consideration of therapeutics. We must not overlook the man who had the disease. Success in therapeutics depended often upon the recognition of the individuality of the case and of the varying factors that made themselves manifest in the symptoms. In treating disease special attention should be paid to restoring normal metabolism, the conditions of which varied in different individuals. The treatment must be modified to fit the man himself. The blood changes should have special consideration. The variations in specific gravity might have a wider significance than was usually recognized. The alkalinity of the blood, the physical appearances of

DR. GEORGE C. STOUT,

Secretary of the Section in Laryngology and Otology.

matory condition of the laryngeal mucous membrane, those of the acute catarrhal form accompanied by thickening of the mucosa, those of a secondary septic process complicating zymotic diseases, and, lastly, those of an infectious nature. The line could not be sharply drawn between the last two forms. The group included those in which the larynx was secondarily involved. The prevalence of epidemic influenza furnished examples of this disease, and there was about it something favorable to the development of œdema in the mucous membrane of the pharynx and larynx.

Total Extirpation of the Thyreoid Gland.—Dr. G. F. Cott, of Buffalo, reported two cases. In the first case there were difficult breathing, a rapid pulse, and a swollen thyreoid. A two-per-cent. solution of eucaine was used and tracheotomy performed. As it was impossible to pass a cannula, a catheter was inserted and passed into the larynx. The next day, thirty hours later, the operation was performed. At first eucaine was used, but, the pain becoming intense, chloroform was given. It became necessary to use a salt solution with nitroglycerin during the operation. After three hours the gland was removed. It weighed five ounces and a half.

In the second case, one of papilloma of the larynx, the patient rebelled against the use of instruments. She was a girl of five years, who had worn a trachea tube for

the red cells (shriveled, crenated, nucleated), and the proportion of hæmoglobin and hæmatin were also important, as was the proportion of the different forms of leucocytes. The state of the blood plasma, as regarded its density and constituents, had an important bearing upon disease, especially with relation to osmosis and coagulability. Calcium salts in the blood favored coagulation. One thirteenth of the body weight was blood (except in the obese and in children). This was constantly in motion and required the expenditure of considerable force. Rest in the horizontal position lessened the burden upon the circulatory apparatus. The distribution of the mass

DR. N. S. DAVIS, JR.,

Chairman of the Section in Materia Medica, Pharmacy, and Therapeutics.

of blood might be irregular and local congestions or anæmias result. In normal individuals the thyroid gland supplied a vasodilator and the suprarenals a vasoconstrictor agent. Increase in secretion of the thyroid gland might produce functional disturbances without the well-marked lesions of Graves's disease being demonstrable, while, on the other hand, the decrease of thyroid secretion and predominance of function of the suprarenals may produce high tension, arteriosclerosis, and atheroma. Too high tension called for exercise, warm baths, free catharsis, small doses of thyroid gland daily, nitroglycerin, or small doses of chloral. In malignant infectious there was a sudden loss of a large proportion of red cells, causing symptoms of acute anæmia ("medical shock"). In the opinion of the writer, every case of typhoid fever would do better with the tincture of chloride of iron than without it, just as in erysipelas and diphtheria. During convalescence from any acute disease there was a condition of vasomotor ataxia. Measures to educate the peripheral vessels to react normally, such as massage, electricity, gentle exercise, sponging, and baths, were valuable in overcoming this condition.

Dr. Coakley said that he had resorted to parenchymatous injection of normal salt solution into a hepatized lung during acute lobar pneumonia, with benefit and recovery.

Chronic Myocarditis.—Dr. John H. Musser, of Philadelphia, made a verbal communication on this subject. He confined his remarks to the form of the disease associated with sclerosis of the coronary arteries, and excluded the conditions of myocarditis occurring in acute disease or due to other causes. It was in fact identical with chronic endocarditis of the coronary arteries. The treatment was divided into hygienic and medicinal management. The latter would depend largely upon associated lesions. It was necessary to regulate the conduct of life as regarded business responsibility, active exercise, baths, diet, clothing, and sleep in each case, correcting arrhythmia, high tension, deficient excretion, etc., so as to avoid attacks of angina or lessen their severity. He especially advocated nitroglycerin, gradually increased until physiological effects were produced. Iodide of potassium was of great value. Conditions of acute arrhythmia and arystole gave the clinical appearance of acute œdema of the lungs, but were due to chronic myocarditis, to which treatment must be directed. Small doses of morphine, hypodermically, with strychnine and nitroglycerin where there was apparently increased arterial tension, in other cases morphine and strychnine without nitroglycerin, were very effective in relieving this condition.

Dr. Beatty, of Philadelphia, in discussing this paper, agreed to the hygienic management, but disagreed as to the medicinal treatment. He had found the greatest service in these cases from the use of a derivation of digitalis.

Dr. Solly, of Colorado, said that high altitudes were not suited to these cases.

Dr. Tomkins, of West Virginia, inquired of the reader of the paper how he managed to give iodide of potassium without disturbing the digestion and causing nausea.

Dr. Musser replied that the best method was to give it in milk. Some preparations of pepsin were also useful. Some patients could take only one dose a day, others had to intermit for several days at a time. He had never been able to get good results from hydriodic acid as a substitute.

The Treatment of Obesity.—Dr. Henry Stern, of New York, read a paper on this subject. He recognized several forms of abnormal increase of the body weight. The influence of diet and bodily activity was insisted upon. In the treatment he dwelt upon regulation of habits as well as medicinal measures. In starting the treatment most stress should be laid upon passive and resistance movements, faradism, massage, and mechanotherapy; in short, all methods contributing toward the improvement of the circulation will be followed by beneficial results. Cold hydropathic procedures resulted in unusual oxidation of fatty material, and the systematic performance of easy gymnastics was not to be neglected in hydroplasmic obesity medicinal treatment. For the heart, strychnine, for the blood, iron, were most useful, with naphthol, bismuth salicylate, or hydrastis canadensis for the intestinal tract. To overcome constipation, saline enemata, podophyllin, leptandrin, and calomel should be used. The thyroid, as a rule, was contraindicated.

The Treatment of Neurasthenia.—Dr. Harold M. Meyer, of Chicago, read a paper in which he dwelt par-

ticularly upon the necessity of correct diagnosis, especially between this condition and hysteria. The diagnosis must always be made by exclusion. The symptom of fatigue and actual deficient muscular power was an important characteristic of neurasthenia. Rest was important, but the so-called rest-cure, applied indiscriminately, did much harm. Primary, or essential, neurasthenia was to be distinguished clinically from the secondary neurasthenia of acute diseases, such as typhoid fever. Strychnine was the best medicinal agent. Psychological treatment was of great importance.

In reply to questions, Dr. Meyer said that the fatigue symptom was the most important diagnostic sign. All cases of neurasthenia were not pure, but might be complicated with hysteria. In the diet, he preferred milk and cream. He used no proprietary or prepared foods. Cold was a very powerful nerve stimulant, and he has observed good effects from having patients sleep in a cold room.

(To be continued.)

Section in Surgery and Anatomy.

The Cause of Diffuse Peritonitis Complicating Appendicitis, and its Prevention.—The chairman, Dr. A. J. Ochsner, read a paper with this title. He reviewed the anatomical and pathological relationship existing between the appendix and the adjacent organs, and referred to the manner in which the appendix was protected and the enormous blood supply of the omentum. The value of rest as a preventive of the extension of infection in any part of the body could not be over-estimated, and if this was gained another important point was secured in the right direction. Infection of the general peritoneal cavity was caused by disturbance of the intestines. Theoretically and practically, food and cathartics should not be taken into the stomach. The reader cited cases in which the ingestion of these substances had greatly irritated the condition. His mortality in cases of perforative peritonitis had been less than one fourth as high as in patients operated on at once; in cases of diffuse peritonitis there had been a great decrease. From January, 1898, to May, 1901, he had operated in 565 cases of appendicitis with twenty deaths, a mortality of three and a half per cent. The danger of rupture of the circumscribed abscess into the general peritoneal cavity had been a cause of great anxiety. There was increased safety in operating during the quiescent state, and as a result of this treatment fecal fistula never resulted. The laity should be taught to stop feeding and giving cathartics to patients suffering from abdominal diseases.

Remarks on the Surgery of the Spinal Cord, with Illustrative Cases.—Dr. Andrew J. McCosh, in his paper thus entitled, said he believed that pressure on the cord was urgent reason for operating, and that early operations were important. He was of the opinion that it was wiser to do the exploratory operation, and that there the danger was slight. It was our routine procedure to cut down on the skull to find out if any fracture was present. If relief was to be expected, an operation should be done at once. In his own laminectomies for fracture of the spine, comprising six cases, two patients had recovered and four had died, but not as a direct result of the operation. He did not think it was necessary to apply any special support to the spinal cord.

Spina Bifida, with a Report of an Interesting Case.—In a paper by Dr. Paul F. Eve thus entitled the author

said that, associated with spina bifida, were hydrocephalus, talipes, and hare-lip. There might be a tumor, varying in size from that of a marble to that of an adult's head, occupying the central portion of the canal over the posterior aspect of the vertebral column. There were three varieties of this affection: Meningocele, the protrusion consisting of fluid in the spinal cord; meningo-myelocele, in which there was a portion of the cord in the sac; and syringomyelocele, the central part of the spinal cord being dilated. Various remedial measures had been suggested, such as acupuncture, injection of iodide of potassium, etc. Extirpation was unjustifiable in young

DR. J. N. UPSHUR,

Secretary of the Section in Materia Medica, Pharmacy, and Therapeutics.

infants, and the indications for operation were where the child was over seven years old and where the tumor was rapid in its growth and rupture threatened.

The Methodical Exploration of the Brain for Fluid was the subject of a paper by Dr. Christian Fenger. He reviewed the literature of traumatic brain abscesses and spoke of the efficacy of the aspirating needle. He described a case having a previous history of suppurating disease of the ear, an attack of appendicitis subsequently, of short duration, and then swelling of the elbow joint. He explored the brain methodically, going from one place to another. There was a cicatrix behind the ear, which was the only guiding point. After exploring the brain on the affected side of the head with no results, he then tried the opposite side, where the pus was found, and the patient recovered. He said that methodical exploration of the brain was preferable to all others. Puncture, he said, was harmless, as Spitzka had previously proved in the needle tracings in the brain, which were aseptic. The author's paper was elucidated with photographs, instruments, and human skulls.

The Immediate and Remote Effects of Brain Injury.

—In a paper with this title Dr. D. S. Fairchild dealt with the value of first symptoms in determining the nature and extent of the lesion, the bearing on the question of treatment and prognosis, the possibility of the lesion

DR. ARTHUR SWEENEY.

Chairman Committee on Arrangements.

being more or less serious than was indicated by the apparent gravity of the early symptoms, the danger of being misled on these points, the remote effects of trauma on the integrity of the brain tissue in producing epilepsy and mental impairment, and falls from a height or from a rapidly moving train. If the first cause of intracranial hæmorrhage was rupture of the middle meningeal artery, the immediate effect thereof was considered serious, unless surgery intervened. The author reviewed scar proliferation from scars of the brain and said that these cases were amenable to surgical treatment. He presented the question of liability and the medico-legal aspect of cases of brain injury.

A Contribution on the Subject of Operation for the Relief of Tic Douloureux, or Trifacial Neuralgia, differing from the operations now in vogue, in that it depended for its success upon the division of the sensory root of the ganglion, and not upon the removal of the ganglion itself, was presented by Dr. Frazier, of Philadelphia, who very interestingly covered the besetting difficulties with which the surgeon met the technic of the operation, and its applicability in the cases under consideration.

Dr. W. W. Keen, of Philadelphia, believed the time had come when cases of spina bifida should be submitted to operative treatment. In relation to Dr. Fenger's paper, he was sorry that he had limited the exploration to searching for pus. There should be a very clear distinction made in exploring the brain for pus, purulent matter, or serum. Ten years ago he had proposed a methodi-

cal operation and formulated several routes by which the ventricles could be reached. He cited several interesting cases of exploring the brain for fluid. As to Dr. Fairchild's paper, he thought the author had taken the right ground, that interference was imperative. He reviewed the phenomena of the state of unconsciousness produced by trauma.

Dr. McLean agreed to Dr. Fairchild's idea of going without support; he had found it difficult to keep the support on. He thought it was a good step, in spina bifida (Dr. Eve's paper), to attempt closure at the operation without aspirating or injecting of fluid. He believed the skull was elastic and compressible in both young and adult, as was proved by clamping it; the tissue within must change and there must be movement within. The spinal canal was not merely a bony canal, but made up partially of fibrous tissue. He referred to concussion and compression of the brain and subsequent extradural, subdural, and cranial hæmorrhage. Now, he thought, there was another point where one might have depression of the skull. In that case, one might first have a compression there and in time the symptoms of that compression would disappear. In that case the cerebral fluid would escape from the cranium, lessen the cranial tension, and escape into the spinal cord.

Dr. Weir did not believe that we had yet arrived at a conclusion with regard to depressed fractures of the skull without symptoms. In regard to wounds of the scalp, he had recently changed his ideas—he did not now let them alone. Surgeons feared, in penetrating the dura, making adhesions; adhesions must be expected. The speaker advocated the use of celluloid plates at the time of operation or at a secondary operation.

Dr. Frank had tapped the lateral ventricles as early as in 1890 with good results. He did not agree with Dr. McLean that, if a person was hit on the head, it would draw the fluid into the spinal column; it was not necessary to receive a blow on the head to become unconscious or give symptoms of concussion.

Dr. Earl was of the opinion that the time was at hand when surgical treatment for injuries to the skull must be employed.

Dr. Moore believed in the surgical treatment of spina bifida rather than injections.

Dr. Dawbarn related an interesting case of a man who was struck on the side of the head and had symptoms of hemiplegia. Operating on the paralyzed side, there could not be detected a clot or anything abnormal. At the autopsy, however, on the side opposite to that affected, there was revealed an enormous blood clot.

Others who joined in the discussion were Dr. Bernays, Dr. Maxwell, Dr. Means, Dr. Crile, Dr. Tagart, Dr. McKnight, Dr. Baldwin, and Dr. Vaughan.

(To be continued.)

Section in Diseases of Children.

Chairman's Address. By Dr. Samuel W. Kelley.—It is recommended that either the office of secretary be made more continuous than at present or that the secretary be provided with an assistant; also that the custom which appears to expect the chairman of the section to act as toastmaster at the section dinner should undergo a revolution.

The advancement of the surgical side of pædiatrics is very important, and has been slower in its development

than was medical pædiatrics. Its advance may be measured in many different ways: by the recognition of the necessity for and importance of it; by the increase of actual knowledge concerning it; by the spirit of knowledge through text-books and teaching; by the extent and

off by the breath and secretions. No age is exempt from an attack of measles. Recurrence of the disease is not uncommon, especially among children. The pathology of the disease is not marked. The period of incubation is now well established, and is found to be about fourteen days from the time of exposure. The prodromal symptoms last about three days, and are associated, later, with catarrhal symptoms. Fever is always present, coming on as early as the second day; often remitting, and rising again just preceding the eruption; laryngeal cough, drowsiness, loss of appetite, and vomiting usually occur; sometimes, also, convulsions. On the third or fourth day, eruptions appear; usually preceded by the Koplik spots, which disappear as the eruption progresses. When the rash begins to disappear, if the fever continues, look for complications; for in complications lies the danger of measles. Bronchopneumonia, intestinal catarrh, hæmorrhages from the mucous surfaces, and otitis media may occur as complications. The diagnosis is not usually difficult, but is occasionally puzzling in isolated cases. Cases without eruption have been reported; malignant forms sometimes occur; marked typhoid symptoms accompany some of the fatal cases; or the disease may awaken a dormant tuberculous condition. The mortality is low, except in complicated cases. The treatment should be hygienic and symptomatic, with rest.

Dr. Slagle stated that he rarely found the Koplik spots. Second attacks of measles had not been common in his experience, but usually when a second attack was diagnosed as measles, it had been found that it was German measles.

Dr. Scott thought rubeola a distinct disease, very much more prevalent than measles, but very easy to confound with the second attack.

Dr. J. M. Postle was sure that he had seen true measles undoubtedly recur, in several cases, and had found benefit in the treatment of measles from the internal administration of suprarenal gland.

Dr. Barber called attention to the danger of endocarditis following measles. Dr. Townsend pointed out that the enlargement of the postauricular glands was pathognomonic of German measles.

Pathology and Treatment of Pertussis. By Dr. J. M. Postle.—Pertussis is a toxic neurosis produced by bacteria, probably by those of Czaplowski, Hensel, and Koplik, working in the tissues beneath the mucous membrane of the respiratory tract. These bacteria produce a toxine which has as the point of special selection for attack those nerve cells governing expiration. These nerve cells are depressed with resulting clonic spasm of the expiratory muscles. Excess of carbonic-acid gas in the blood produces powerful stimulation of the nerve cells governing inspiration, at the same time partially or completely destroying the toxine. Children, therefore, when playing around gas-works, have whooping-cough lightly. Dr. Rose, of New York, has treated pertussis by rectal injection of carbonic-acid gas, and this experiment has seemed to ameliorate the symptoms. The whooping sound is produced by inspiration before the laryngeal muscles are fully relaxed. There is a prompt return of the expiratory cells to normal when the toxine has been destroyed by rational therapeutics. Immunization and recovery are complete in from one to three weeks, depending on how near to the full physiological effect the patient is kept while under the influence of the remedies used. The treatment consists of the administration of suprarenal gland tissues, strychnine, or any preparation of nux vomica, which may be given hypodermatically or

DR. SAMUEL W. KELLEY,
Chairman of the Section in Diseases of Children.

the manner in which this knowledge is applied in practice. When thus measured it becomes evident that many of the most prominent writers on surgery have given inadequate attention to the surgical side of children's diseases. At the present time the knowledge of anatomy, physiology, pathology, and the history of diseases has reached such a point in the observations of practical physicians and surgeons that the diseases of children, their peculiarities, and their importance can no longer be quite ignored by the surgical side of the profession. There is now needed no elaborate argument to prove that there is a department of surgery as distinct from that of adult life as the medical diseases of children from those of their elders. In the cases of children abnormalities are found, and the same diseases occurring in adults are marked by different phenomena when occurring in children. We are aware what peculiarities surround operative work upon children. How ill they bear hæmorrhage, cold or prolonged shock, and how wonderfully they recuperate when once the stress of the storm is past! In medical journals, medical societies, and medical teaching, too little attention is paid to the surgical subjects. There should be, if necessary, the child's surgeons as well as his physicians; or at least the surgeon should be required to extend his knowledge to the special surgical diseases of children.

Measles. By Dr. J. B. Garber.—The prime cause of measles is no doubt a specific poison, the nature of which has not been fully determined. The poison spreads by contagion from one person to another and is given

by the stomach, and should be pushed almost to the full limit or slightly toxic effect.

The Antenatal Treatment of Hæmophilias. By Dr. J. W. Ballantyne, of Edinburgh, Scotland. Read by Dr. Darnall.—Cases in which the effect of antenatal treatment can be tested are few and far between. Hæmophilia is clearly and persistently hereditary, and shows a family prevalence. The probability is that male offspring will be hæmophilic, though the female offspring usually escapes. There is a presumptive diagnosis then of antenatal hæmophilia when a woman coming from a family whose males are hæmophiliacs is pregnant of a male infant. The following case is reported: Mrs. C., thirty-four years of age, third pregnancy, tall, well built, rather spare, with black hair, sallow complexion, has always lost much blood at her menstrual periods and had *post-partum* hæmorrhage after both confinements. She has a distinct family history of hæmophilia and the first child at birth was white and anæmic. It is still alive, but is a marked "bleeder," having nearly succumbed several times during the cutting of its teeth; the second pregnancy ended in the birth of a male child and was also associated with a *post-partum* hæmorrhage. The infant showed hæmorrhage from the umbilical cord at birth and died at the age of twelve months, during dentition, the cause of death being returned as cerebral hæmorrhage. The mother was now pregnant for the third time. I advised that treatment with calcium chloride might safely be given to the mother, and that this drug would pass through the placenta and reach the fetal

ried out for three months. On October 3, 1900, a male child was born, red and mottled and healthy in appearance; indeed in all respects normal; there was no hæmorrhage from the cord, no *post-partum* hæmorrhage, for the first time in the mother's obstetric history, and she was able to nurse her infant. The labor was easy, and the whole process normal. Since that time, the infant has never had any bleeding, and does not bruise like his brothers. He has also cut a tooth without a hæmorrhage, while it may be noted that his eldest brother still suffers with a bleeding tendency very markedly. This may be a coincidence, but if so, it is a very remarkable one, and we cannot accept the conclusion that it is merely a coincidence. There are circumstances which encourage the opinion that, after all, the treatment in this case may have had something more than a coincidental relation to the healthy state of the third infant.

A Case of Pyloric Spasm in an Infant.—Dr. C. Herrman reported such a case, having first seen the infant at the age of five weeks. The child was breast fed. In the third week vomiting began, coming on after each nursing. The vomitus was not bile stained. Epigastric peristalsis was noticed. There was persistent constipation, and progressive loss of weight for five weeks. The infant then took a sudden turn for the better. There was less vomiting and gradual recovery. At present the age of the child is seven weeks. It is very small, but fairly well developed.

SYMPOSIUM ON TYPHOID FEVER IN CHILDREN.

Symptoms of Typhoid Fever in Infancy and Childhood. By Dr. J. P. Crozer Griffith.—The author reviews a number of articles that have appeared on typhoid fever in the last few years. The symptoms of typhoid fever in children differ in many respects materially from those seen in adults. To insist that the cardinal symptoms must always be present would lead us into frequent errors in diagnosis. The affection is far from rare in infancy and the failure to recognize it is rapidly disappearing, because we are more on the alert for it, and have the serum reaction test to aid in the diagnosis. The peculiarity of the onset of typhoid in children is its indefiniteness. The great degree of malaise and fatigue is absent. There are loss of appetite, slight indisposition, and some headache. The temperature does not abate, and, although the child scarcely feels ill, the diagnosis of typhoid fever may be made by exclusion. The child is sent to bed on general principles and not because it wants to go. In the second class of cases the onset is sudden, with vomiting and with fever from the start, and the rash is discovered. In infants the symptoms are vague because elevation of temperature is common from slight or undiscovered causes. Perhaps only the Widal reaction will distinguish the disease from indigestion, enteritis, or influenza. Another peculiarity is that the course of the disease is shortened, from fourteen to twenty days being, perhaps, an average length. Abortive cases are common, and it is milder than in adult life and the mortality is lower. Children under five years are less liable to die from it. The roseola is quite as common as in adults. In a few cases I have seen herpes labialis. Desquamation is described by the French writers as occurring frequently. Enlargement of the spleen is usually present, but not usually discovered. There is perhaps nothing peculiar in the respiration. The pulse is often unusually slow as compared with the rate that one would expect for the same elevation of temperature in other diseases. The temperature curve is similar to that in adults. Not infrequently it

DR. WILLIAM EDGAR DARNALL,
Secretary of the Section in Diseases of Children.

tissues, although theoretically the hopes of success were small; also that iron, arsenic and strychnine might be administered in order to improve the general health, increase the tone of the uterine muscle, and lessen the risk of *post-partum* hæmorrhage. This treatment was car-

rises rapidly without the step-like ascent. Often it remains high without the tendency to morning fall. Toward the end of the attack it falls, often with much greater rapidity than in adults. Indeed, the fall may be almost critical at times. The tongue is not so liable to become dry and parched. Vomiting is a very common initial symptom. It is sometimes troublesome even later in the disease, occasionally directly producing death. Diarrhoea is more likely to be absent than present. Abdominal distention is not often a troublesome symptom, though frequently present. Hæmorrhage is of rare occurrence. When it does occur it is usually in later childhood. Perforation is also of uncommon occurrence. The infrequency of these two symptoms is probably due to the less pronounced development of intestinal lesions. One of the characteristics is the tendency of nervous symptoms to predominate over the intestinal symptoms. Extreme torpor, coma vigil, and carphologia occur much less often than they do in adults. Slight delirium is common, especially at night. A certain degree of apathy is very common, especially in very young children. A condition sometimes seen is that of pseudomeningitis; this sometimes causes confusion in diagnosis. Meningitic symptoms, it is true, do occur in the typhoid of adults, also, but certainly less characteristically. As a rule the diagnosis can be easily made, but sometimes typhoid fever begins in children with all the appearance of acute leptomeningitis and leads for a time to an entirely erroneous diagnosis. Aphasia is a nervous symptom rather to be considered as a complication and occurs probably more frequently in childhood. The discussion of the complications and sequelæ is probably beyond the scope of this paper and will not be entered into.

The Diagnosis of Typhoid Fever in the Laboratory.

By Dr. John Lovett Morse.—The author, before taking up the subject to be discussed, protests against the separation of laboratory and clinical methods in the diagnosis of typhoid fever. They should not be thought of separately, but together. Both are fallible and both should be used understandingly, with due recognition of their limitations, or erroneous conclusions will be arrived at. The value of the various laboratory tests is unequal. Some are easy to carry out, some are difficult. All have their limitations. The Widal reaction is present in ninety-five per cent. of all cases of typhoid fever. It seldom appears before the second week. In a small number of cases it may never be present. In others it may be intermittent. Repeated negative tests are very strong evidence against typhoid fever. The reaction may persist in the blood so long as twenty-nine years after recovery from typhoid; hence a positive reaction in the absence of other symptoms is not diagnostic of typhoid, unless one can be sure that the patient has never had typhoid. A negative reaction, followed by a positive reaction, in a dilution of one to fifty, is absolute proof of typhoid. The Widal reaction appears in children under the same conditions as in adults, but it appears earlier, is feebler, and persists for a shorter time. It is of exceptional importance in aiding in the diagnosis of typhoid in children, its especial value being, first, in ruling out many cases of gastro-intestinal disease; and, secondly, in clinching the diagnosis in mild cases that might be possibly overlooked. In infancy the reaction is of less value than in older children and adults, because it may be transmitted to the infant through the mother. The agglutinating power may be transmitted, not only when typhoid is present during pregnancy, but

DR. C. A. WHEATON.
Of Committee on Arrangements.

even when pregnancy takes place years after recovery. When transmitted through the milk it does not persist for more than a week. Examination of the stools has shown the presence of the typhoid bacilli in from three to five days after the patient has taken to his bed. The test is considered by the author as of nearly equal value with the Widal reaction. The examination of the feces requires a complete laboratory and much expert knowledge, and is, therefore, not practicable for the average general practitioner. Typhoid bacilli may be found in the urine in from twenty to thirty per cent. of the cases. They do not usually appear in the urine until late in the disease; in a few cases, however, they have been demonstrated before the appearance of the Widal reaction. Recent observers have shown that about eighty per cent. of cases show typhoid bacilli from an examination of the blood, which is usually withdrawn from the veins of the arm, fifteen to twenty cubic centimetres of blood being used. On account of the complicated processes and the technical knowledge required, the test is hardly practicable. In a series of comparative tests the rose spots almost invariably showed the presence of the bacilli before the appearance of the Widal reaction, usually five or six days before. The spots must be carefully excised, however, under antiseptic precautions and the cultures immediately made. The Diazo reaction is simple and can be made by anyone. It may be obtained in most cases of typhoid, often appearing early. As it is also present in tuberculosis, septicæmia, and other febrile diseases, the very conditions with which typhoid is easily confounded, it is of comparatively little value. The leucocyte count is important. It is subnormal throughout the entire course of the disease. The average number is 5,000 to the cubic millimetre, or even less. The increase in the number above normal means some com-

plications, such as hæmorrhage or inflammation, or some outside influence, such as cold bathing. The value of the leucocyte count is only seen when the diagnosis lies between two diseases, one of which has leucocytosis and the other has not, as in typhoid and septicæmia, the latter having a leucocytosis and the former not having it. The diagnosis of typhoid made in the presence of an almost inexplicable leucocytosis is almost invariably wrong. If there is some serious complication, as perforation or hæmorrhage, there will be other symptoms to corroborate it. If a diagnosis is desired from malaria the examination of the blood for the plasmodium malarix will clear up the doubt. If from meningitis, lumbar puncture should be resorted to. The author concludes that the Widal reaction and the leucocyte count are the most important of the laboratory methods in diagnosis

DR. J. W. CHAMBERLAIN.
Chairman of Committee on Badges.

of this disease, because they are practicable and easily carried out. Other tests, although perhaps more accurate, are at the same time impracticable.

Report of a Case of Typhoid in an Infant.—By Dr. Francis E. Barrett.—The author first discusses the slowness of the practising physician to recognize the fact that typhoid really does occur in infants. The report is of interest on account of the age and physical condition of the child; the absence of many of the common symptoms, as enlarged spleen, rose spots, coated tongue, and prodromal symptoms, and the continued high temperature without morning remissions. The patient was a boy, aged two years and four months, and had always been physically weak. He had never made any use of his legs. His digestion was weak and there was a certain tendency to gastro-intestinal catarrh. On the first day of the disease the child seemed as well as usual in the morning,

but in the afternoon he suffered from pain in the head and nausea and vomiting. The temperature was 103.4° F. Lungs clear, breathing quick, no râles present, heart's action rapid and strong, and the heart sounds clear. The spleen was not enlarged and the liver was normal, but there was a slight tenderness over the abdomen. During the first night he passed urine only once, about thirty cubic centimetres in amount, and this was obtained after a long-continued application of hot fomentations over the bladder and kidneys. The urine had a peculiar odor, educed Fehling's solution, and also responded to Nylander's test for sugar. Albumin not found. Diazo reaction absent. Under the microscope nothing was to be seen but a large number of amorphous urates. Respirations frequently reached as many as sixty to eighty a minute. No urine was passed the second night, and the abdomen was distended and sensitive to pressure. Hot applications were effective and gave relief. The temperature now went to 104° F., and did not fall below this point until the end of the first week. A faint diffuse erythema was noticed on the third day. The Widal reaction was found at the end of the first week. The tympanites was distressing, there was marked weakness, and noticeable loss of flesh. The temperature began to fall about the tenth day and the child began to have a ravenous appetite. On the twenty-second day, for the first time, there was no evening rise of temperature. The treatment consisted of cold baths, cold packs, and irrigation of the colon. Small doses of antipyrine were given the first day. Antisepsis was accomplished by salol and calomel. Turpentine stupes and egg-and-turpentine injections were used. The diet was largely beef broth, chicken broth, and barley water; later, fruit juice and oatmeal gruel. Malted milk produced vomiting; fresh milk, predigested and with lime water, was also employed.

Treatment of Typhoid Fever in Children. By Dr. Henry E. Tuley.—The author considers first the great importance of trained nursing. It is next to impossible for a mother, beset with the cares and responsibilities of a household, and especially if there are other children, to properly care for a patient sick with typhoid fever. The dietetic treatment is important. Milk is unsuited for a regular diet. Broths may be given, whey, predigested milk, some of the cereals and the concentrated foods. No regular routine of medicinal treatment is possible. The treatment should be largely symptomatic, giving only such medicines as are absolutely essential. Jugulation is not possible. No antipyretics should be given internally. The condition of the heart should be jealously watched, and strophanthus and strychnine administered if it begins to flag, while all alcoholic stimulation should be reserved for administration late in the disease. For the condition of flatulence and tympanites, turpentine stupes are very useful, when this drug cannot be given internally. Diarrhœa may be controlled by bismuth. In considering other conditions of serious import, it must not be forgotten that the care of the mouth is essential and important. In hydratic treatment excellent results have been obtained. Full baths, however, are rarely possible in private practice, but frequent and prolonged sponging gives almost equally as good results. The author concludes with the remark that it is only by eternal vigilance, and with competent and skilful nursing, that these cases are brought through and restored to health.

(To be continued.)

AN X-RAY STUDY OF THE
CAUSES OF DISABILITY FOLLOWING
FRACTURES INVOLVING THE ELBOW JOINT.*

By SAMUEL LLOYD, M. D.,

NEW YORK,

PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL
SCHOOL; ATTENDING SURGEON TO THE NEW YORK POST-
GRADUATE HOSPITAL AND TO THE BABIES' WARDS;
ATTENDING SURGEON TO ST. FRANCIS HOSPITAL.

FRACTURES in the vicinity of joints are dreaded by the general practitioner even more than simple fractures along the shafts or bodies of the bone. Fractures in the vicinity of the elbow, being usually more common than fractures near or involving other joints, are always looked upon with special interest. It should be an in-

ments even in an approximately correct position. Third, that ankylosis will result in a certain number of cases in spite of all care on the part of the surgeon and no matter what plan of treatment may be pursued.

In the *American Medico-surgical Bulletin* for November 1, 1894, I published an article on arthrotomy for deformity following fractures involving the elbow joint, in which I advocated cutting down on these deformities and removing the obstruction to the motion. At the time this paper was read before the Lenox Medical and Surgical Society of New York I presented a boy upon whom I had operated during the previous summer. He had had a fracture of the external condyle of the humerus, which had been treated with the arm but slightly flexed. There was a range of motion of only about ten degrees, so that the arm was practically useless.

When the joint was cut down upon, it was found that

FIG. 1.—Supracondyloid fracture of the humerus, showing over-production of callus.

variable rule to warn the patient and his friends, in the presence of witnesses, that there is very decided risk of the motion of the joint being impaired, perhaps completely lost. The most painstaking study of the causes of this interference with motion has not enabled us to adopt measures of treatment that will absolutely prevent its occurrence.

Three things are thoroughly well recognized in fractures into the elbow joint: First, that it is not always possible to tell, even under an anæsthetic and with the most careful examination, just what the injury is. Second, that it is not always possible to replace the frag-

ments even in an approximately correct position. Third, that ankylosis will result in a certain number of cases in spite of all care on the part of the surgeon and no matter what plan of treatment may be pursued.

In the *American Medico-surgical Bulletin* for November 1, 1894, I published an article on arthrotomy for deformity following fractures involving the elbow joint, in which I advocated cutting down on these deformities and removing the obstruction to the motion. At the time this paper was read before the Lenox Medical and Surgical Society of New York I presented a boy upon whom I had operated during the previous summer. He had had a fracture of the external condyle of the humerus, which had been treated with the arm but slightly flexed. There was a range of motion of only about ten degrees, so that the arm was practically useless.

When the joint was cut down upon, it was found that

*Read before the Medical Society of the State of New York, January 30, 1901.

FIG. 2.—Supracondyloid fracture of the humerus.

consequence of the youth of the patient, it was impossible to get him to exercise the joint sufficiently, so it was twice necessary to break up the adhesions under ether, but he has now almost a normal range of motion, flexion and extension being only slightly affected.

Other surgeons about this time had begun to advocate the operative treatment of this condition, and some had applied it to compound fractures. In the latter cases there could be no question that it was the proper mode of procedure, and Murray showed to the New York Surgical

Society and published in the *Annals of Surgery* (March, 1894, page 336) a notable case. This patient, a man, fell from a scaffold, a distance of fifteen feet, striking on the back of the left elbow. When he was first seen, twenty-four hours after the accident, the soft parts were greatly swollen and lacerated, and behind and to the inner side of the elbow was a wound where the upper fragments had perforated the skin. On enlarging the wound, there was found a transverse fracture passing a short distance above the condyle, and from the centre of

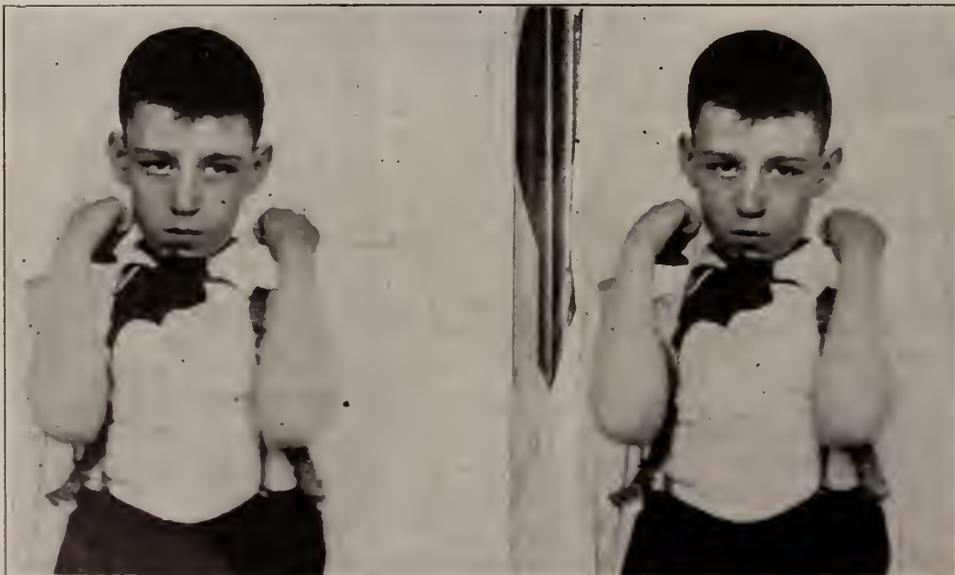

FIG. 2a.—Result after treatment, showing full flexion.

FIG. 2b.—Result after treatment, showing extension.

his transverse line a vertical fracture extended into the joint. The external condyle was drawn upward in front of the shaft, and the internal condyle was displaced inward by the olecranon, which was wedged upward between the condyles. An incision two inches and a half long was made over and exposing the external condyle; holes were drilled through the shaft and external con-

dyle; a strand of kangaroo tendon was passed through the holes and tied and the condyle was thus brought into position. The olecranon was then drawn down into place and the internal condyle reduced. With the aid of an aneurysm needle, a strand of kangaroo tendon was passed through the outer wound, behind the condyles, then around the internal condyle, and then in front and

FIG. 3.—Supracondyloid fracture of the humerus.

back to the point of entrance. The ends were tied over the external condyle, and thus the internal condyle was held in place. The wounds were left open, packed with

Powers, at the meeting of the New York Surgical Society of November 22, 1893 (*Annals of Surgery*, Vol. xix, 1894, page 236), presented a boy, nine years of age

FIG. 4.—Separation and inward displacement of the lower epiphysis of the humerus. Inward dislocation of the radius and ulna.

iodoform gauze, and a right-angled splint was applied. They were dressed anew on the third day, but the iodoform gauze was not removed for eleven days. Passive motion was employed at the end of the fourth week.

who had complete ankylosis in extension following backward dislocation of the ulna, fracture of the coronoid process, and considerable callus. Arthrotomy was performed, the callus chiseled away, and the dislocation re-

FIG. 5.—Separation and displacement, inward and backward, of the lower epiphysis of the humerus. Dislocation of the radius and ulna.

Flexion and extension were nearly perfect, and supination and rotation were completely so. The arm is nearly as strong as before the accident.

duced. At the end of four months after the operation the range of motion was from 90 degrees flexion to 110 degrees extension.

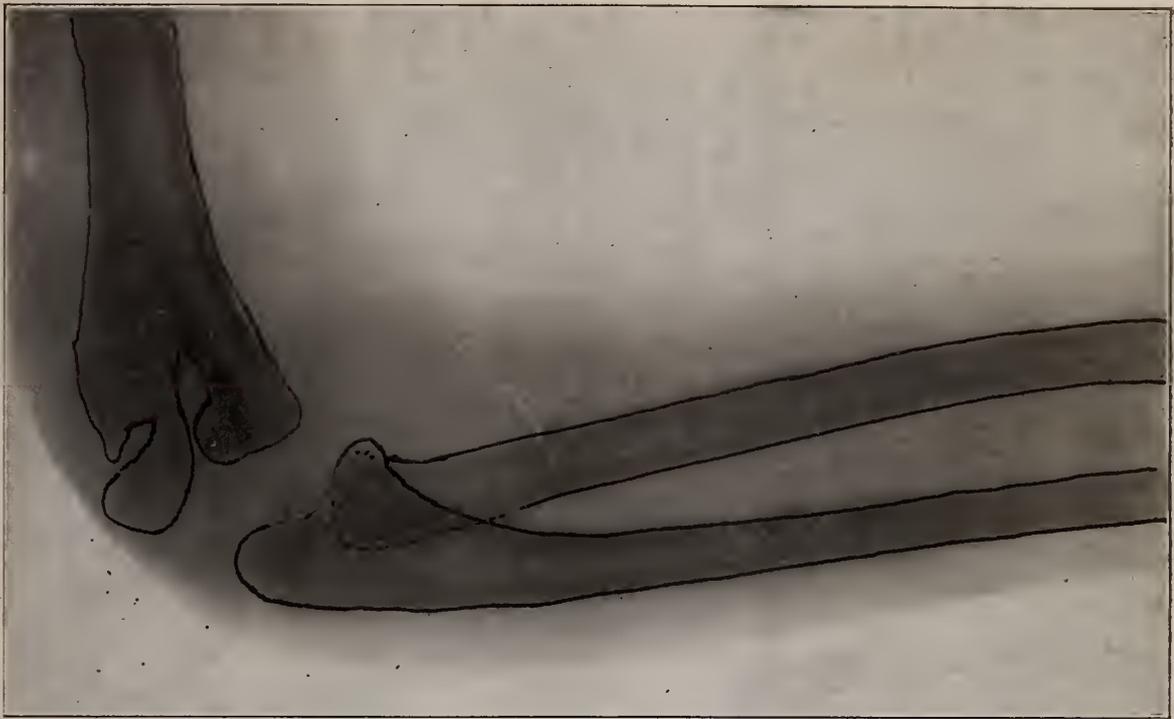

FIG. 6.—Intercondyloid fracture of the humerus. Incomplete fracture of the external condyle.

Wight (*Annals of Surgery*, Vol. xviii, 1893, page 218) has reported ten cases of ankylosis of the elbow joint after treatment of fracture of the lower end of the humerus with the forearm in the extended position. Five of these patients were operated upon, excision of the lower end of the humerus being performed. In four re-fracture was accomplished, while in one an operation was declined.

Klemm (*Sammlung klinischer Vorträge*, No. 78, September, 1893) recognized the possibility of an operation being resorted to, but said that it should be reserved for those cases in which there was an injury to the soft parts already, or in which without suturing it was im-

possible to secure reduction of the fragments with proper coaptation.

Mollière (*Revue de chirurgie*, November, 1886) advocated, in connection with irreducible dislocations of the elbow, partial or complete resection of the end of the humerus.

Deces (*Revue de chirurgie*, 1886) had successful results following arthrotomy in two cases of irreducible dislocation of the elbow.

Maydl (*Revue de chirurgie*, 1886) had treated five old dislocations of the elbow in this way.

Stimson (*Annals of Surgery*, Vol. xviii, 1893, page

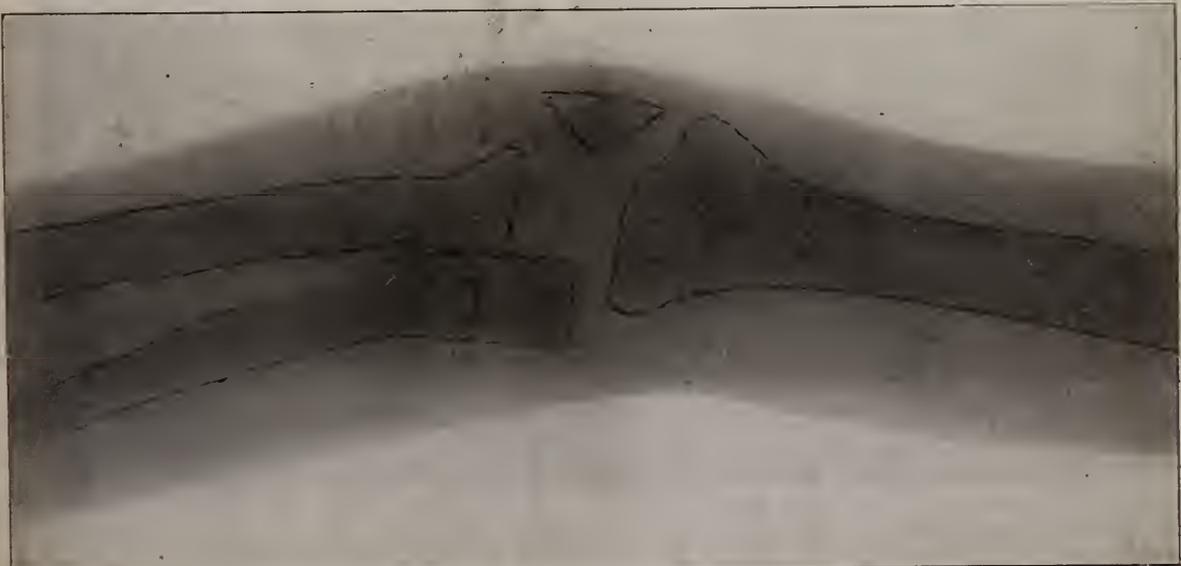

FIG. 7.—Separation of the capitellum and dislocation inward of the radius and ulna.

666) has also advocated the open method in irreducible dislocations.

Moore (*Medical Record*, Vol. xlv, 1893, page 583) advocates, when the fragments of the humerus at this joint are so displaced that they cannot be reduced by

sion. He thinks they are caused by trauma. One and perhaps a common method of production is by the chipping away of pieces from the coronoid process or olecranon process of the ulna, as illustrated in Fig. 10.

Oberst (Volkman's *Sammlung klinischer Vorträge*,

FIG. 7a.—Result obtained after operation, showing flexion, separation of the capitellum, etc.

manipulation, cutting down upon them at once, under proper aseptic precautions, reducing them through the open wound, and then wiring them in place.

Koenig (*Deutsche Zeitschrift für Chirurgie*, Bd. xxvii, H. 1 and 2) operated in three cases of free bodies

No. 311) says that the most frequent causes of ankylosis are:

1. The prolonged rest of the joint in the treatment of the fracture.
2. The inflammation following traumatism.

FIG. 7b.—Showing extension after operation. Fracture of the capitellum, etc.

in the elbow joint. Extension was limited, and the bodies could be demonstrated before the operation. They were found in the anterior pocket of the joint on the ulnar or radial side. The symptoms were synovitis and sudden pain, pain in motion, and an incomplete exten-

3. The over-production of callus.
 4. The ordinary intracapsular and extracapsular blood extravasation associated with the fracture.
- These were the results of clinical experience and practical observation up to the time of the discovery of

FIG. 8.—Fracture of the internal condyle of the humerus with lateral dislocation of the radius and ulna.

the Röntgen ray. At this time we hoped that all uncertainty in regard to fractures would be overcome, but, unfortunately, we have been compelled to recognize the fallibility of the ray in surgical work. It is not always possible to make out a line of fracture by means of the fluoroscope, and in the hands of untrained experimenters many mistakes result from not recognizing the fact that the image thrown on the plate or screen is only a shadow, and these shadows may be made as unreal and as fantastic as the shadows we cast upon the wall with our hands for the amusement of children. This has made the work with the x ray not a pastime, but a serious undertaking and a special study requiring trained operators to obtain accurate results.

It is an essential nowadays, since the x ray has illustrated how frequently the fractures are comminuted or complicated with partial or complete dislocation, that every fracture of the elbow should be examined carefully under complete anæsthesia. Then, and then only, can one be even moderately hopeful of completely reducing the fragments. The accompanying series of pictures illustrates some of the conditions we may expect to find and some of the conditions that we should strive to obviate. This series is not made up of pictures taken at the time of the injury, but in almost every instance they represent cases that have come under my observation because of limitation of motion.

None of these has been treated in our service for the

FIG. 9.—Fracture of the internal condyle of the humerus. Lateral dislocation of the radius and ulna.

FIG. 10.—Fracture of the internal condyle and chipping of the olecranon.

FIG. 11.—Fracture of the radius below the head.
(Skiagraph by Dr. E. R. Corson, Savannah, Ga.)

fracture, yet it is far from me to criticise the result save in those cases in which the straight position was maintained. In general practice, in the hands of the practitioner who does not have abundant opportunity for treating and observing fractures, I do not believe the straight position of the arm should ever be maintained when treating elbow-joint fractures, except in the case of the olecranon process of the ulna.

Figs. 1, 2, and 3 represent three cases of supracondyloid fractures of the humerus. In the first the arm had apparently been treated about midway between flexion at a right angle and complete extension (about 145 degrees). The photograph shows the condition accurately. The condyles were carried backward while the shaft of the bone was drawn forward. It is evident that in this case if the bones were placed in proper position they were not maintained there. The shaft of the humerus is seen projecting forward so that in flexion the coronoid process of the ulna strikes upon the mass of callus below the more prominent projection of the shaft before it reaches the right-angled position, while the ulna would rest upon the sharp end of the diaphysis in complete flexion.

It is perfectly obvious in this case that further flexion was out of the question, and consequently this boy had a useless arm. Extension was possible to the extent seen in the picture. In operating in this case the projecting portion of the diaphysis was chiseled off and a new coronoid fossa was then cut out with a curette until complete flexion was possible. The arm was then maintained in the position of complete flexion. No attempt was made to improve the extension. The result was remarkably satisfactory. In spite of the extensive dissection necessary to reach the anterior surface of the humerus and the consequent laceration and bruising of the capsule and the synovial membrane, flexion was obtained almost to the full extent, so that the patient was able to reach his mouth, ear, necktie, and the collar button in the back of his shirt band.

Fig. 2 represents the good result that may be obtained in a similar case by careful reposition of the fragments. This picture and also the next one (Fig. 3) were lent to me by Dr. C. C. Page, of New York. In the first the excellent functional result obtained is shown by the accompanying photograph. It will be seen that the only deformity in Fig. 2 is the loss of the carrying angle of the right arm. In both these pictures it is evident that without proper replacement of the fragments flexion inside of a right angle would have been impossible, as in both instances the diaphysis would strike directly against the radius and ulna.

Figs. 4 and 5 represent a somewhat similar condition, the separation of the lower epiphysis of the humerus with dislocation of the radius and ulna. From Fig. 4 one would judge that replacement should be comparatively easily effected, but as a matter of fact it was not put back completely and the dislocation of the radius and ulna offered the great interference with the motion. It

was replaced in position by cutting down, refracturing, and cutting away some exuberant callus on the inner surface. I have not seen this boy since he left the hospital, last year, but at that time he had a very fair amount of flexion, well within a right angle, although he was unable to touch the shoulder on the affected side with his fingers. Extension was considerably limited, but my impression was that it would materially improve.

In Fig. 5 we have a similar condition, except that the epiphysis has been completely turned over. In this case it was necessary to make a resection of the olecranon and coronoid processes and smooth off the projecting end of the diaphysis. The functional result was one of the best I have obtained. Fig. 6 shows a splitting, or intercondyloid, fracture of the humerus. The external condyle was also incompletely fractured and displaced backward. Here the olecranon and coronoid fossæ were completely occupied by callus, so that neither flexion nor extension was possible. The motion also was arrested by the displaced condyle interfering with the flexion of the radius. Both fossæ were carefully excavated and the condyle was cut away with a chisel until the radius moved easily. The position of the arm was changed daily on account of the callus in the humeral depression, and the result was a useful arm, though with a decreased range of motion.

Fig. 7 represents a fracture of the capitellum and an internal dislocation of both bones. The mass of callus thrown out about the fractured area was very great and absolutely prevented reduction of the dislocation until it had been chiselled away. It was then possible to force the bones back into their proper position. The range of motion at the time this boy came to me, about two years ago, was very limited, only about 10 or 15 degrees. The flexion was to 145 degrees, giving him a practically useless arm. He now has practically full flexion. The photographs accompanying the radiograph show his condition at the present time.

Fig. 8 shows a fracture of the internal condyle of the humerus with an inward dislocation of both bones of the forearm. In this case a mass of callus rounded out the area between the tip of the condyle and the point from which it was fractured and also filled up the olecranon and coronoid fossæ. The same procedure was undertaken in this patient. The projecting condyle being removed, together with all of the callus that interfered with reduction and with motion, the fossæ were excavated anew, and the result was an improvement in the general condition.

Fig. 9 represents simply another case of the same kind, which was submitted to the same treatment.

Fig. 10 shows an extensive case. There was a fracture of the internal condyle involving the olecranon fossa, and there was also a fracture of the olecranon with a backward and inward dislocation of both bones. The callus was very exuberant and there was only 5 degrees of motion. The arm had been treated in the straight position. At the operation the usual routine was followed

of dissecting away all the callus that interfered with motion and removing any bone that could possibly affect the usefulness of the limb. This is the poorest result I have had. His arm is now flexed at a right angle, but his motion is arrested by a bony point, apparently interfering with the passage of the radius over the capitellum. This prevents complete flexion. I have advised cutting down again and removing the obstruction.

Fig. 11.—This case of fracture of the neck of the radius was most skilfully treated and skiagraphed by Dr. Eugene R. Corson (*Annals of Surgery*, 1899), of Savannah, Ga. It will be seen at a glance that, unless the surgeon had an x ray plant at hand while examining a case of this kind, reposition would not be very probable. The interference with the motion of the joint would then be very great.

This series of pictures is by no means complete, but, if it has the effect of stimulating surgeons to a careful examination of all the cases of impaired motion in the elbow joint, I shall feel that my purpose has been accomplished.

The pictures here shown illustrate forcibly the fact that the bony lesions, displacements, and callus cause most of the disability. If that is so, then nothing is left for the future of the patient except a stiff arm unless an operation is performed. If an operation is undertaken, what will be the result? In my own series of cases I have not had a single case in which suppuration has penetrated the capsule and affected the motion. I do not mean to say that I have had absolutely aseptic results in every case, but I do say that when suppuration has occurred it has invariably been in the skin, and has remained in the skin, never penetrating the joint. As a result I have not had a single case, and I have now operated twenty-one times, in which motion has not been gained instead of lost.

I know of one case of operation by a friend of mine, a very skilful surgeon, and an exceedingly careful asepticarian, in which the joint did become infected, and as a result no motion was gained. The boy's arm, however, was held in a much better position than before the operation.

It is absolutely essential that no sepsis of the joint should supervene. If this can be prevented, and it should not occur if the surgeon carries out the proper precautions, there should invariably be a gain in motion.

A most surprising fact to me has been the demonstration of how little effect extensive injuries to the joint capsule have upon the after-result. The capsule may be cut and lacerated extensively during attempts to overcome deformity by operative measures, and yet a perfectly useful limb will result. So convinced am I of this fact that I no longer dread the effect of operative treatment of the elbow joint so long as no suppuration results. Given a primary union in the scar, and the fibrous ankylosis due to the adhesions will be effectually

overcome by the patient without recourse to painful attempts at passive motion.

We must consider, then, that we have to deal with, first and principally, ankylosis due to interruption of the proper action of the joint by displaced fragments of bone; second, interruption of motion due to exuberant callus along lines of fracture or filling up the olecranon or coronoid fossa; third, fibrous ankylosis due to suppuration, effused blood, or inflammatory changes.

In the *Annals of Surgery*, Vol. xxv, 1897, page 701, Allis says: "Very many so-called simple fractures are as grave as the more dreaded compound fractures, and cannot possibly be scientifically treated by any than open measures. . . . I have seen six fractures of the elbow joint, all simple, that resulted in total loss of function of the forearm and hand, and one of them in the hands of one of Philadelphia's foremost hospital surgeons."

No surgeon would leave a fracture of the shaft of a long bone in mal-position at the present day; if he could not get it into position by manipulation, he would cut down and put it in position. There is no more reason why he should not do it in the elbow joint. I personally should not hesitate a moment about cutting down on a recent fracture about this joint if I found I could not readjust it so that the function of the joint should be preserved. We should not hesitate in a compound fracture, and nowadays there is no reason for hesitating in a simple fracture.

When it is recalled that the elbow is a simple joint, with small articular processes which can be readily reached, that it has a simple synovial membrane and an abundant vascular supply, together with such a powerful set of muscles that if they are not too much interfered with they will of themselves, unconsciously on the part of the patient, favor the regaining of motion, it seems strange that any one should debate the advisability of the operation.

I do not want to be misunderstood on this question, however; this is not an operation to be undertaken at any time and place and by any practitioner of medicine. Unless the operator has a thorough knowledge of the anatomy of the elbow joint and considerable experience in aseptic and operative technique he had better let the case alone.

In my own work I have usually used the same incision as is ordinarily employed for excision of the elbow, a single vertical incision at the back. Sometimes this is placed internal, sometimes external, to the triceps tendon, according to the portion of the joint I wish to reach. Once or twice I have found it necessary to use the H incision when the bony lesion was extensive. The triceps tendon is then pulled to one side and the deeper parts are separated by clean-cutting dissection until the joint is exposed. Of course, it is essential to look out for the ulnar nerve. The joint is then opened and the bony changes are brought into view. The chisel, bone forceps,

and bone scoop are employed to remove the bone, testing motion from time to time until it is certain that flexion is complete. It is very important then to wash out all bony débris from the joint and close the capsule carefully just as one closes the peritonæum. The other structures are then brought into position and sutured. The arm is dressed in the flexed position and retained in that position for a week, when all the dressings are removed, and the patient is encouraged to use the arm. Systematic massage is also useful at this stage.

The essential point in the whole operation is the removal of all bone or callus that in any way interferes with the proper motion of the joint. If both sides of the humerus are operated upon, as when the coronoid and olecranon fossæ are both involved, the arm must be brought down into full extension as soon as possible.

I am in the habit then of putting it up in full flexion, in two or three days extending it as far as possible without pain, and then each day continuing the change of position, with manipulation, until motion is easy and the arm falls readily into either flexion or extension.

A MODIFIED URETHRAL DILATOR-HANDLE.*

By FERD. C. VALENTINE, M. D.,

NEW YORK,

PROFESSOR OF GENITO-URINARY DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE; GENITO-URINARY SURGEON, WEST SIDE GERMAN DISPENSARY, ETC., ETC.

CHRONIC gonorrhœa, post-gonorrhœal urethritis, and urethral strictures continue to be the bugbear of general practitioners, despite all that is being done to make these conditions understood and their treatment rational. There is no need of emphasizing this fact to specialists, to whom these cases are daily referred. In view of the fre-

FIG. 1.—The patient lying on the table, dilator inserted; the patient can see the dial.

quency of chronic urethral disturbances and of the intensity of literature on the subject, it seems surprising that so many acute urethral diseases go over into chronicity and that then so many excellent, well-informed practitioners tacitly place them in the incurable category. In a measure this may be due to the large amount of detail

work required in the treatment of these chronic conditions, and the inevitable absence of quick, brilliant results obtainable.

These elements have not deterred earnest workers from laboring arduously toward the desired end. One need but recall the writings of Kollmann, Wossidlo, and other men to evoke a vista of their numerous followers in the path which Oberlaender first hewed. I have endeavored elsewhere* to present a conspectus of

FIG. 2.—The patient lying on the table, dilator inserted; operator bending over the patient's abdomen to see the dilator's dial.

the work of these able men, with such practical modifications thereof as increased experience developed.

Throughout, it is evident that anything which will simplify the work is likely to induce others to adopt the methods which prove successful in the hands of those who employ them.

The present effort is a small contribution to that end. The years devoted to such chronic urethral conditions as are amenable to treatment by the dilators which Oberlaender and Kollmann devised have led to but one regret. This regret is due to the fact that the name "dilators" has been given to these instruments. In appearance they certainly are dilators; their temporary effect, it is true, is primarily to dilate the urethra's diminished calibre. This dilatation, however, is only an incident to the treatment; its permanent effect, grossly stated, is to cause resorption of pathological infiltrates and thus permanently to set aside the cause and effects of the disease. Much as the misnomer with which these instruments were brought out is regrettable, I deplore that I cannot suggest a short,

*Presented before the Genito-urinary Section of the New York Academy of Medicine, February 20, 1901.

**The Irrigation Treatment of Gonorrhœa, its Complications and Sequelæ.* William Wood & Company, New York, 1900.

comprehensive designation which will better describe their action.

The fact remains, however, that the majority of chronic urethral conditions yield to the employment of

3. The average patient, observing his improvement under this treatment, is likely to apply a vicious twist to the screw, thinking that by hastening the dilatation he accelerates his cure. I regret that in this class are the physicians who come for treatment of their chronic urethral diseases.

The improvement in the handle of the instrument, made from my design by Messrs. Tiemann & Co., consists essentially in having the dial at the top of the instrument and two heavy metal projections for the easy grasp of the operator's left thumb and index finger.

The technique of the employment of this modification and its action in nowise differ from those of the Oberlaender and Kollmann dilators.

The advantages of this modification are:

1. While being guided by the amount of resistance for each increase of dilatation, the dial is continually under

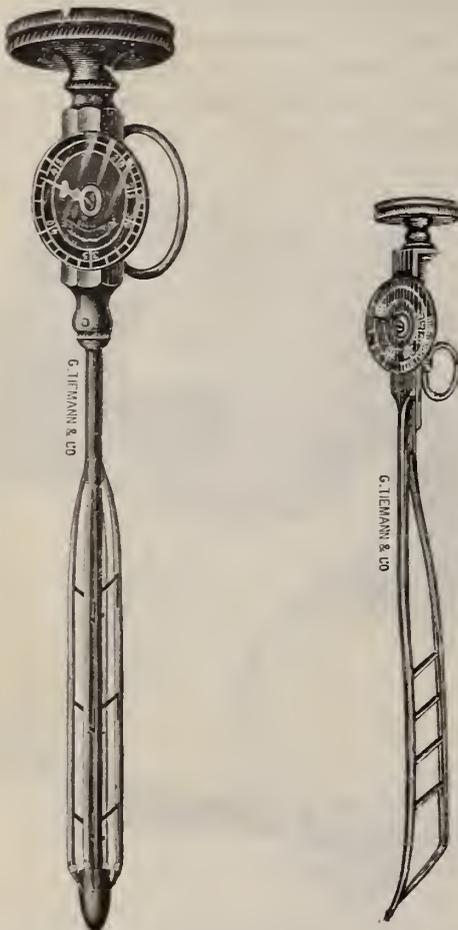

FIG. 3.—Oberlaender and Kollmann dilators, showing the position of the dial.

dilators. While no objection can be made to the efficacy of those of Oberlaender and Kollmann, it has long been evident to me that, without changing the principles of their action, their employment might be made more convenient. Each of these dilators has the dial on one side of the handle. As it is best, for many reasons, that the instrument be used while the patient is in the recumbent position; the dial necessarily faces the patient. The exception hereto is the Kollmann anterior dilator, which, being perfectly straight, allows the dial to face in any direction. With all the others the before-mentioned condition prevails. The principal objections hereto are:

1. The operator cannot control the amount of the dilatation, except by interrupting it, so as to bring his vision in line with the dial. This requires bending over the patient's abdomen. The importance of thus checking the work done at each *séance* is evident when considering the possibilities of danger from too rapid or excessive dilatation.

2. The shield and dial on the Oberlaender and Kollmann instruments do not offer the operator's left thumb and index finger a firm grasp of the instrument, while he gently holds the penis with the other fingers.

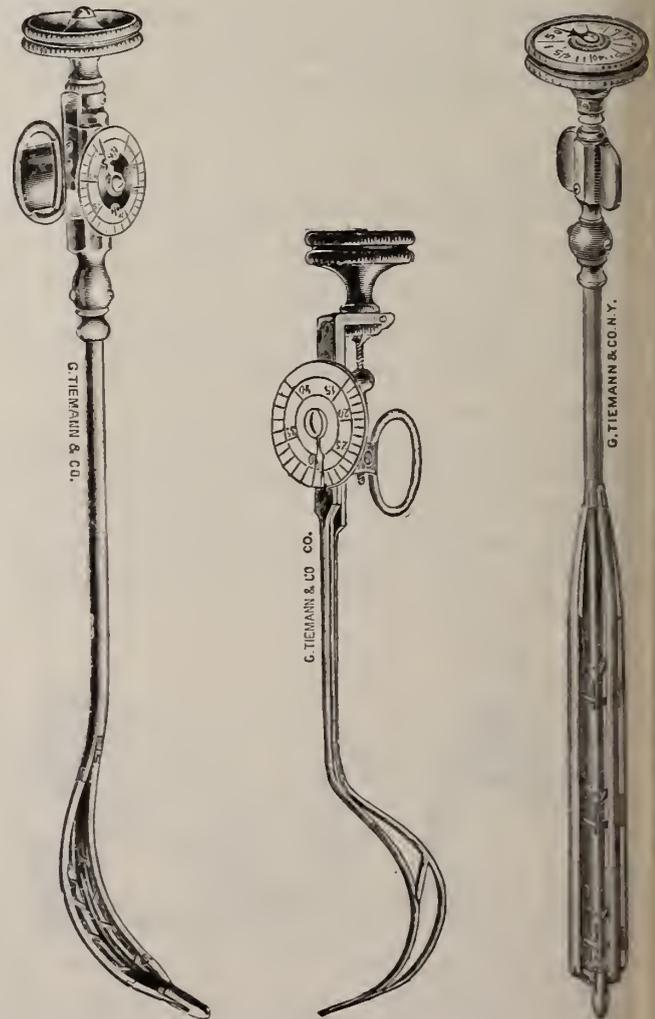

FIG. 4.—Valentine modification.

the operator's eye, positively guarding against any excess of dilatation and making any change of position unnecessary.

2. Having no dial or shield at its sides, this modified dilator is more easily introduced and more easily held in position during its employment.

3. The dial, being beyond the patient's range of vision, offers him no inducement unnecessarily and even dangerously to increase its calibre.

irritation of the nervous system in general or of the nerve centres or the filaments distributed to or controlling the organ in particular being held to be the ætiologi-

FIG. 5.—The manner of holding the penis with the Valentine modification of the dilator.

FIG. 6.—The patient lying on the table, dilator inserted; the operator dilates while the dial is in view.

4. The improved mechanism of this dilator-handle simplifies the construction of the instrument without increasing its cost.

MEDICINE, ETC.

(Continued from page 943.)

Ætiology.—Up to within a late period, *hyperacidity* has been classed among the neuroses of the stomach, an

cal factor. Latterly, however, Riegel, while contending in the main for the same ætiology, admits that in a few instances an irritation of a local character, *i. e.*, direct irritation of the gastric mucous membrane, may lead to this condition.

My own experience, based upon the number of cases already stated, upon a careful scrutiny of their histories, and upon the results obtained in their treatment, compels me to a view directly the opposite to that of Riegel, namely, that, while in a few cases an irritation of the nervous system in general or in part may be the ætiological factor that has provoked the hyperchlorhydria, in the greater number more direct—more tangible—causes can be found to account therefor. These local factors I place, according to their importance, in the following order:

A. *Constipation.* This, contrary to the view generally held, I regard as a most important ætiological factor, and for the following reasons:

1. Careful inquiry into the histories of the patients

coming under my observation disclosed the fact that in all instances where there was any distinct recollection in the matter (a number in whom the malady had lasted for some years had entirely forgotten the particulars of its onset) the constipation antedated the hyperacidity for a varied length of time.

2. Free action of the bowels is always attended with great improvement. All these patients declared that they felt better and suffered but little, or not at all, from pain or burning or acidity of the stomach when the bowels acted freely.

It is to me a matter without doubt that whatever success has been obtained in treatment with the mineral waters rich in the various active salts of sodium is altogether due to their purgative action, and not, as has been maintained, to any mysterious chemical processes developed in the economy. The following history is very illustrative of this:

November 5, 1899.—H. S., a woman, fifty-one years old, a native of Poland, married and the mother of children, height 5 feet 5 inches, weight 186 pounds, consulted me for pendulous abdomen (*Hängebauch*), which she had had since her first pregnancy. The circumference of the belly at its most prominent point was 119 centimetres. About fifteen years before, while still in Europe, she began to have trouble with her stomach. She became constipated, and then followed pressure and burning in the stomach. She was advised to drink the waters of Marienbad.* She took them regularly for long periods, then would intermit, to resume again as she again become constipated. Ten years before consulting me she came to America, and shortly after her arrival her stomach trouble reappeared. She was treated, without much benefit, for two years, and was then advised to go to Marienbad. She took the trip, and was again soon relieved. She remained at these springs for quite a long time, and then returned to this country. At first she felt well, but gradually she became more constipated, and after a time she was again troubled with the pressure, the burning, and the sourness of the stomach. After a few years she made a third trip to Marienbad and was again relieved. She came back here, and three months later all her old symptoms had again returned, and she has been thus afflicted ever since.

3. A normal, regular activity of the bowels once secured, in these cases, by appropriate treatment, and the gastric phenomena disappear very rapidly.

4. A supervening constipation may, in certain persons not otherwise so affected, provoke an attack of transitory hyperacidity, as shown by burning in the stomach, pyrosis, and the ejection of an acrid fluid which numbs the teeth as it passes over them.

As to the mode of action of constipation, I explain it in this wise: Long-continued constipation (referring here only to that dependent upon atony of the intestines) leads to atony of the stomach, *i. e.*, its motor activity is impaired; the gastric muscle does not perform its function with its normal rapidity and force. This is readily

understood if it is remembered that the impulse to gastric motion comes from the intestine. In consequence of this slowing of movement, the chyme is retained unduly long and becomes, in a measure, an irritant; its presence stimulates the secretory activity of the organ, more gastric juice than is requisite for the chymification of the quantity of food ingested is poured out, and the hydrochloric-acid element of the excess, remaining free, irritates the gastric mucous membrane and gives rise to the characteristic manifestations. Perhaps a gastric juice with hydrochloric-acid element stronger than normal is poured out. This process being repeated several times, a habit on the part of the stomach is formed (every part of the human being as well as the whole can take on a habit), and the morbid condition known as hyperacidity established.

B. *Alcoholic Liquors*.* It is not at all necessary that they should be indulged in to excess; even a moderate use, long continued, may lead to hyperacidity. That an indulgence to excess in the strong liquors, such as brandies, whiskeys, etc., may produce a hyperacidity is possible; I believe, however, as a matter of observation on alcoholics, that in the majority of these cases a condition of chronic congestion, perhaps a subacute inflammatory condition with superirritability of the gastric mucous membrane, is established rather than excessive secretion, and that the symptoms are due to the former rather than the latter.

C. *Smoking*. Tobacco-smoking is considered by some as of ætiological importance. Though it is admitted that with some persons smoking has a stimulant effect upon the gastric mucous membrane and may thus cause the secretion of gastric juice, I do not believe that *per se* it plays much of a rôle in the production of hyperchlorhydria; it is only when its irritant effects are superadded to those of the alcoholic liquors that it can be considered to have any causal influence. This much, however, is beyond doubt, that once an irritable condition of the gastric mucous membrane is established, smoking is a very powerful factor in maintaining it—nay, in adding to it.

D. Food of very heavy character, very rich food, food that has become gamy or in which irritant substances have developed may occasionally excite a hyperchlorhydria of transitory or chronic form.

Another ætiological factor referred to by both Bouveret and Riegel is *the withdrawal*, for any reason whatsoever, of its usual diet from a stomach accustomed to heavy food, food rich in nitrogenous material, and the substitution therefor of a much simpler and much lighter diet.

Under these circumstances, I certainly should not consider the case as one of hyperacidity, taking the term to signify a morbid state. In fact, there is no hyperacidity here. The stomach is not at all at fault; it is prepared to do the work to which it has long been accustomed; it is the individual who is at fault, in that he does

*Kreuzbrunnen or Ferdinand'sbrunnen, rich in sulphate, bicarbonate, and chloride of sodium.

*a. Brandies, whiskeys, gins. b. Wines, mainly tart Rhine wines. c. Exceptionally only, beers.

not supply to it material of the usual character. The stomach accustomed to the rich, heavy foods and providing for their digestion by the secretion of an abundant supply of gastric juice, containing all the proper elements thereof, cannot accommodate itself on the instant to the more abstemious diet, cannot at once inhibit the secretory function in the measure required by the changed character of the ingesta.

This is no more hyperacidity than is the want of stool in the starving constipation, though it is so classed, as I have pointed out elsewhere.*

Rapid eating, imperfect mastication, eating food too hot, or drinking fluids that are too cold, and highly spiced food are all said to be frequent factors in the production, through local irritation, of hyperacidity. So far as my own observation goes, none of these has played any rôle herein. The first two, which, as they always go together, are really one, are among the most frequent causes of indigestion and of subsequent gastric and intestinal atony; but the indigestion is of the character that is dependent upon a lowering of the hydrochloric-acid element of the gastric juice from its normal proportion—an insufficiency. The latter factors, with the exception of the last, which I have not encountered in any form, I have always found provoked a gastritis of a more or less acute character, never a hyperchlorhydria.

E. In a number of cases it is undoubtedly some disturbance of the nervous system that is the direct cause of the hyperchlorhydria. It may be either a disturbance of the nervous equilibrium, as we find it in hysteria and neurasthenia, or some form of cerebral irritation dependent upon prolonged worries, excessive cares, or emotional disturbances of various natures. Mental overwork is also said to lead to hyperacidity. In my experience it has generally been associated with a dyspepsia of an atonic character, a lowering of force, both secretory and motor.

As will be readily understood, the nervous phenomena are here decidedly prominent. In the hyperchlorhydria of such causation the constipation that attends some of these cases is occasionally of most obstinate character. As already stated, I hold that it is a result of the ætiological factor, and not merely a consequence of the hyperacidity. In proof thereof it will be found that the constipation is very much of the character of the ætiological factor. If the nervous derangement is of a light form that yields readily, or the mental worry or irritation is readily obviated, the constipation will likewise be of mild type and yield readily and quickly to treatment; if, however, the nervous trouble is of a graver form—has a stronger hold upon the patient—the constipation will also be of obstinate character and require long and persistent and varied treatment before an impression is made upon it.

The comparative frequency of these various ætiological factors may be judged more correctly, because expressed in figures, by a study of the following table, the summing up of causation in the twenty-three cases here referred to:

Constipation.	11 cases
Drinking and smoking.	6 “
Nervous disturbances of the various characters above referred to.	5 “
Food of very heavy, and perhaps irritant, character.	1 case

Not infrequently it is a combination of various of these ætiological factors, rather than a single one, that has led to the development of the ailment. Thus, we may have smoking, drinking, and constipation combined, or smoking and drinking and eating of heavy dishes, or smoking and cerebral irritation, or constipation and a tendency to neurasthenia or hysteria, etc. Usually one of these stands forth prominently and is of greater ætiological importance than the others; nevertheless, to achieve success in treatment, they all must be attended to, must be obviated or removed. As the old maxim has it, *sublata causa, tollitur effectus*.

Pathological Anatomy.—So far, with the rare exception of a slight erosion, both macroscopical and microscopical examination of the stomach, post-mortem, have shown no deviation from the normal. From clinical evidence, however, I am inclined to believe that a more or less irritated condition of the gastric mucous membrane exists, but that it disappears with the setting in of the fatal illness, when all that has tended to maintain it is set aside, and is therefore not apparent after death.

Diagnosis.—The diagnosis cannot be made upon any one symptom or any one group of symptoms. The finding in the examination of the stomach chemismus of a high total acidity, even with a large percentage of free hydrochloric acid, does not necessarily mean a hyperchlorhydria. As already stated, I have seen cases in which the quantity of free hydrochloric acid was as large as in any of the twenty-three cases forming the basis of this study, and still there was no hyperacidity, even as none of the other manifestations of this morbid condition was present.

The other features, already discussed in detail, that the stomach contents are said to present are as yet too much in question—the why and wherefore too little understood—to have any bearing on this point. This is apparently the view of Riegel, for, though the investigations with regard to them were made by his former assistant, a gentleman whom he otherwise frequently refers to by name, he does not mention them in this connection, in any way, in his latest work on *Diseases of the Stomach*.*

Neither can gastralgia or pain or burning or acidity in the stomach be counted upon as a certain indication of this morbid condition. I have seen cases (and so undoubtedly have others) of gastralgia—in one instance the

*See Illoway, *Constipation in Adults and Children, with Special Reference to Habitual Constipation and its Most Successful Treatment by the Mechanical Methods*. The Macmillan Co., 1897.

*See *Bibliography*.

most severe I ever met with—wherein the hydrochloric acid element of the gastric juice was either greatly deficient or wanting altogether. I have heard patients complain of severe pain in the stomach, and still examination of the chemismus disclosed an absolute absence of free hydrochloric acid. I have heard complaints about burning in the stomach (one patient said it seemed to her as if she had a fire within her), and upon examination hydrochloric acid was found altogether wanting, the burning depending upon the free development of sarcolactic and lactolactic acid, butyric acid, and other volatile acids. Likewise have I seen cases of acidity (of the stomach) in which this was due altogether to freely developed lactic and acetic or other acids.

It is only when we have all the symptoms together, the high total acidity, the large percentage of free hydrochloric acid with gastralgic paroxysms, with the pain described, with the burning, with the acidity, that we can make a diagnosis of hyperchlorhydria.

I consider the gastralgic paroxysm, the pain in the stomach, the burning in the stomach, the acidity thereof, as the stigmata of hyperacidity; for only when these are present (one or several) can we justly conclude that the percentage of free hydrochloric acid found is an abnormal one, that too much of it is poured into the stomach.

In cases with gastralgic paroxysms, and more particularly when the pain is located to the right of the median line, in the neighborhood of the gall-bladder, a distinctive diagnosis will have to be made as regards biliary colic (without icterus). However, no great difficulty need be encountered here if it is borne in mind that the pain, the gastralgic seizure, stands in close relation to the ingestion of food, as already described, while the attacks of biliary colic are altogether independent thereof. Furthermore, a very distinguishing feature is this: The patient with the gastralgia or pain of hyperacidity can always eat. The spasmodic seizure over, frequently even during the same, he can eat and he wants to eat and usually does eat a rather hearty meal. The sufferer from biliary colic has no appetite, does not want to eat, and cannot eat; a little thin fluid to moisten his parched mouth and throat and to revive him somewhat is all that he wants.

Complications.—The complications noted in the twenty-three cases were:

1. *Atony.* Some degree of atony of the gastric muscle was noted in six cases. It was determined mainly by the splashing sounds heard after the ingestion of fluids, as will be set forth in detail elsewhere.

2. *Gastroptosis* was noted in but one case.

Consequences, or sequela, observed.—*Erosions* were noted in but one case, and even in this instance there was no evidence thereof at the time the patient came under my observation, no flecks of blood, no fragments of mucous membrane. The diagnosis, in so far as this point is concerned, was based upon the statement of the

patient that now and then, at more or less long intervals, he had noticed a fleck of blood in the regurgitated liquid.

Treatment.—Of the twenty-three cases forming the basis of this paper, eighteen were under observation a sufficient length of time for me to note the effects of the treatment; the five other cases were seen but once or twice (after the completion of the examination), and I have not learned whether in them any results were obtained or not.

The treatment that I direct, based upon the views as to the nature, the aetiology, and the pathology of hyperacidity herein enunciated, is rather a simple one, decidedly more a matter of omissions, and has always, so far as I have been able to observe, proved eminently successful. The two indications to be met are: A. the removal of the cause or causes. B. The cure of the ailment.

The measures employed to meet these indications have been the following:

A. The removal of the cause or causes.

1. *All alcoholic liquors, of whatsoever nature, are prohibited.* Even beer was subsequently included in the prohibition; for, though some of the patients alleged that they could take it without experiencing any after-effects therefrom, I became convinced, nevertheless, that in the majority of instances, and particularly if taken in any quantity, it helped to keep up the trouble.

2. All smoking of tobacco in whatever form (pipe, cigar, cigarette) is strictly interdicted.

3. All acid or acidulated drinks are forbidden.

4. All foods or condiments prepared with vinegar or lemon juice are forbidden.

5. All sharp condiments (pepper, black or red, ginger, the various sauces) are strictly prohibited.

These rules apply to all cases, without distinction as to original causation.

When patients are *constipated*, they are treated by the mechanical method, by massage, as described in detail in my book on *Constipation*, and with an appropriate dietary as there indicated, modified, however, to meet the exigencies of the special ailment here under consideration.

I never prescribe the alkaline saline waters or the bitter waters proper, for the reasons already indicated, namely, I do not believe in their supposed mysterious influence as regards the hyperacidity, and, as to the constipation, hold, as is common consensus, that they are directly injurious, tending to make it more profound, more obstinate, even as do other purgatives.

Where a disturbance of the nervous equilibrium (neurasthenia, hysteria, etc.) presents itself, appropriate measures and remedies (hydrotherapy, the valerianates, asafoetida, etc.) to right this are employed.

It must be added here that there seems to be much interdependence of the one trouble upon the other, and *vice versa*. With the relief from the distressing sensations in the stomach, the nervous system very quickly recovers its normal tone.

B. The cure of the ailment. Of the first importance as to this is a proper diet, for, properly constituted, I hold that it has a decidedly curative action. I direct my patient to take a good breakfast, a very fair lunch (noon), and a regular dinner (evening).* If he has any desire to eat before going to bed, and many have, I allow him a sandwich or a glass of milk with a cracker.

In these meals the preponderating element is always some one or more articles of the nitrogenous group; in fact, this is the meal, the other dishes being but adjuvants. I do not at all favor the views set forth by some, that the carbohydrates should constitute the main element of the meal. I can see no reason therein. The carbohydrates stimulate the secretion of gastric juice, as well as articles of the nitrogenous group, and this is clearly demonstrated without looking very far by the Ewald and Boas test breakfast, without having the capacity to take up the great part thereof, and thus a considerable quantity of the hydrochloric acid constituent of the gastric juice is left free in the stomach to irritate the gastric mucous membrane.

The articles of the nitrogenous group that I direct for the diet are milk, eggs, and meat (preferably beef and mutton). The meals are constituted thus:

Breakfast.—Milk, two hard-boiled eggs, cold, and cold bread and butter; or milk, steak or chops, and cold bread and butter.

When the patient is constipated, a dish of stewed fruit, prunes or prunes and figs, precedes the meal.

Tea and coffee are, as a rule, prohibited, for both excite gastric secretion, but cannot take it up. Milk can take up and bind an enormous quantity of the hydrochloric acid constituent, as has been shown by Leo, and as I have amply convinced myself by clinical investigation. Furthermore, it forms a sort of coating over the gastric mucous membrane, and this tends to ward off any irritating action the secreted juice might have thereon.

The only exceptions I make as to this are fat-persons, to whom milk is not appropriate, and those who, from some innate idiosyncrasy, cannot take milk. For the former, weak tea or coffee with an addition of one third or one fourth milk; for the latter, milk with an addition of one third to one fourth tea or coffee is allowed.

Lunch.—Chops or steak, roast beef or roast mutton, bread, and water. If desired by the patient, a boiled potato or a small dish of stewed rice or of oatmeal (according to the solubility of the bowels) is allowed. If the patient has had meat for his breakfast, the lunch is made up of two hard-boiled eggs, cold, milk, and bread and butter.

Dinner.—A little soup, plain boiled fish (if desired), roast beef, roast mutton, roast chicken (only occasionally), a baked potato, a small dish of some vegetable, and a pudding (without any acid sauces) or a dish of stewed fruit. The meat to constitute the bulk of the meal. To persons accustomed to it (and who would otherwise miss

it very much) a little black coffee (about two tablespoonfuls) is allowed at the end of the meal.

The sandwich, referred to above as allowed before going to bed, is a meat sandwich made of cold beef, cold mutton, cold chicken, or ham.

The rules for the preparation of the food are these:

1. All vegetables to be prepared after the plain American fashion; that is, they are first boiled in water and, when sufficiently soft, are taken out and sliced or hashed up, put into some meat broth, and allowed to come to a boil. No fats, no browned flour allowed therein.

2. All meats to be either broiled or roasted or stewed. All fried meats are prohibited.

3. All fried food, of whatever nature, is prohibited.

Rules as to eating:

1. All foods, when eaten, must be only moderately warm. All hot dishes, of whatever character, are absolutely prohibited. No hot bread or hot cakes of any kind allowed.

The meals, as thus constituted, I believe to have a curative action in this way:

1. If they are prepared and eaten according to the rules laid down here, all irritation of the stomach is avoided.

2. Constituted as they are, they can take up all the gastric juice secreted and bind the hydrochloric acid constituent thereof, preventing it thus from doing harm to the gastric mucous membrane.

3. Eaten abundantly, as the patient is encouraged to eat them, they tend to allay the excitation already established and thus to the cure of the trouble. This I conceive to be accomplished in this wise: Hyperacidity is the result of an over-excitation of some form of the secretory apparatus of the stomach. Now, if the organ is given an abundance of work, a certain degree of exhaustion of secretory capacity will naturally follow this, and with it an abatement of the over-excitation must in due time ensue.

I allow nothing in the nature of food between the meals. When patients can take such meals as have been here described, I am absolutely opposed to their taking any food, be it even of so light a character as a glass of kumyss or of plain milk, in the interval. I do not fear the emptying of the stomach; on the contrary, I court it in all cases. It must get through with the first meal before another is taken. It is a matter of clinical experience with me, and I have made it the rule of my practice that this organ must have proper intervals of rest if its functional integrity, particularly as regards its motor function, is to be properly maintained, and that all deprivation of such rest is followed by an atony of the muscular structures, and if continued will terminate ultimately in marked atonic distention. It certainly cannot get the needed rest if fresh food is ingested before that previously taken has been duly disposed of.

Before discharging the patient, I impress upon him that, to make the relief permanent, the prohibitions must

*This is the custom here.

be adhered to, and the dietary rules must be strictly followed by him for a long time—not less than a year.

Medication.—In uncomplicated cases I employ no further medication than this, if medication it can be called, namely: I direct the patient to take half a glass of natural Vichy water (French) at the hours already referred to in the Symptomatology, to wit, between 10 and 11 or at 11 in the morning and between 4 and 5 in the afternoon. When dinner is had late, and nothing more eaten thereafter, a third half a glass of Vichy is taken just before going to bed.

The purpose of this is to relieve the distressing sensations in the stomach as they manifest themselves at the times named, and to neutralize any acid that may have remained therein after the evening meal, so that all cause of irritation throughout the night may be removed. Till now it has invariably succeeded.

With strict adherence to the course of treatment here mapped out, the distressing sensations become ameliorated, become attenuated, come on at longer intervals, and finally disappear altogether. I have found that in almost all instances the afternoon paroxysms were the first to disappear, and then later on the mornings became free from distress.

The patients, I find, usually abandon the drinking of the Vichy, as the need therefor ceases, of their own accord, in the same order that the paroxysms leave off; at first the afternoon Vichy is abandoned, and later on the morning dose is discarded. When the Vichy is thus being left off, with or without direction from me, I have the patients, particularly those with a tendency to constipation, take the same quantity of plain water in its stead. It cools the stomach, facilitates the removal therefrom of the débris, and favors the solubility of the bowels.

When atony, with or without distention, or gastrop-tosis complicates the trouble, I prescribe, in addition to the treatment as already set forth, tincture of nux vomica. The rationale of its action is apparent and need not be discussed further. Frequently I combine with it Fowler's solution, on account of the inhibiting influence of the latter upon the development of gases. The medicine is directed to be taken two or three times daily, immediately after meals. I am certain that it is of the greatest benefit, and that it influences and hastens in a marked measure the success of the treatment.

(To be concluded.)

PENETRATING WOUNDS OF THE ABDOMEN.

BY RUSSELL S. FOWLER, M. D.,

BROOKLYN,

ADJUNCT TO THE SURGEON IN CHIEF, BROOKLYN HOSPITAL; ASSISTANT SURGEON, METHODIST-EPISCOPAL HOSPITAL; SENIOR ASSISTANT SURGEON, GERMAN HOSPITAL, BOROUGH OF BROOKLYN, NEW YORK.

ASIDE from whatever injury may be inflicted upon the abdominal viscera, the mere fact that the abdominal

covers have been penetrated and the cavity of the peritonæum invaded by a foreign body is of grave import. The classical and time-honored custom of immediately probing wounds of this class cannot be too highly condemned. Nor should the finger be employed. Treated rationally and intelligently, in the majority of these cases the patients can be saved.

Every wound of the abdominal wall should be regarded with suspicion. The amount of external oozing should be noted. If no oozing is evident, has the blood formed a hæmatoma in the tissues, or has it escaped into the peritoneal cavity? Determine all the facts obtainable in connection with the injury; in which direction the blow was given, the variety of weapon, the depth of penetration. Investigate every detail that may throw light upon the extent of the injury or point to the organ involved. While such contributory evidence as is outlined above is valuable, yet its significance should not be over-estimated.

Method of Examination.—The greatest precautions must be taken in every case, as those cases which apparently present fewest difficulties may, in the end, offer the gravest complications. It is of primary importance to remove the patient as speedily as possible to a place where every detail of asepsis and antisepsis can be observed. The operator should be one who is a master of abdominal technique. Above all, the wound should not be explored in any manner until everything is ready to proceed with a laparotomy if needful. Neither probe nor instrument of any kind should be allowed to touch the wound. Provisional suturing should not be done. Prolapsed viscera should not be handled, nor should they be returned. The only indications which are to be met at the scene of the accident are the stimulation of the patient if shock is present, the protection of the wound from further infection by the application of a snug-fitting, copious, sterile dressing, and the patient's rapid yet non-disturbing removal to a place which offers all advantages for his subsequent well-being. When such a place has been reached, the patient is carried at once to the operating-room unless his condition is one of such considerable shock that immediate operative interference is contraindicated. The necessary instruments are sterilized. Murphy buttons should be included, for one cannot tell whither the exploration will lead nor what lesions may be discovered in its course. It is enough that there is upon the surface of our patient's abdomen a small, red, gaping wound indicating a stab wound, or a dark spot with blackish, discolored edges indicating a bullet wound. An absolutely hopeless condition of the patient is the one thing which shall deter us from pursuing an investigation into the destruction of tissues of which the small tell-tale mark is the clue. If our exploration has been undertaken early, before the anæmia of hæmorrhage or the profound depression of peritoneal intoxication has become evident, we may hold out fair hope of a successful issue. There is one rule in the treatment of abdominal

injuries in civil life which should be a law—explore. The doctrine of immediate intervention should always be observed. This field of the surgeon's work offers a higher mortality than any other, and why? Because of the damnable conservatism displayed by the general practitioner and in many instances by the so-called surgeon. That the patients themselves are to blame in some cases is beyond dispute. We have all seen cases of grave abdominal injury in which, though an operation has been urged, the patients have delayed until too late to submit to superior judgment. These are extremely ignorant people who cannot be brought to realize the danger of their position. All we can do for such is to explain and advise, and if our efforts prove unavailing, retire from the field, conscious that we have done all that lay in our power. But in the case of our medical brother the situation is different. Here there is no excuse for ignorance or superstitious fear. Men who would not delay an instant in putting a typhoid patient on a suitable diet, or in clapping a tourniquet around a bleeding and mangled limb, will, in the case of a stab wound or bullet wound of the belly, give morphine and await developments. And then, when it is too late for human aid, they will call in their surgical brother. Some patients get well, because in every case penetration has not occurred into the peritoneal cavity and, if so, it has not caused serious injury. But who is the Cagliostro of modern times who can prognosticate with such precision? If such exist, let them obey their Hippocratic oath and give their secret to their fellow-practitioners, to the greater benefit of man. Explore every abdominal wound. The wound of the slender stiletto may well inflict more damage than the butcher's cleaver.

The skin is shaved and scrubbed from the nipple line to the middle third of the thigh. The scrubbing is done briskly, yet carefully, so that no spread of peritoneal infection or increase of hæmorrhage results. The cleansing is completed with oil of turpentine, alcohol, ether, and, finally, bichloride of mercury. The skin around the wound is painted with tincture of iodine to still further protect against infection. The wound itself is cleansed by swabbing with sponges wrung out of antiseptic solutions. Sterile sheets and towels cover the patient, except at the site of operation. The operator, nurses, and assistants are dressed and have their hands and arms prepared as for any laparotomy. Then, and not till then, is the wound explored. The edges of the wound are gently retracted and a silver probe is introduced. Delicately this probe is inserted until the depths of the wound are reached, or until its further passage is obstructed, or until it has beyond peradventure entered the peritoneal cavity. In both the former events the wound tract is laid open freely enough to permit of identification of each layer of aponeurosis and muscle through which the examining instrument has passed. It may be that the probe, in spite of the delicacy with which it has been introduced, has entered the wall of the wound tract at some point instead of following the latter. If so, the

free laying open of the tract will develop this. Identify each layer and examine thoroughly. Finally, we reach the lowermost part of the wound. Here the greatest care must be exercised. The wound in the peritonæum, if present, may be very small. If the peritonæum at the bottom of the wound tract is normal in appearance, if there is no blackening or discoloration of its surface, if the intra-abdominal parts look normal as seen through the parietal peritonæum, if no aperture is present, and, finally, if these findings agree with the other evidence in the case, then one may redisinfect the wound and close it, layer by layer, suture the skin, and apply a copious gauze dressing and a snugly fitting binder. By so proceeding, the surgeon averts the danger of sepsis and of ventral hernia, which latter follows many of the incised wounds of the musculo-aponeurotic planes of the abdomen.

On the other hand, if, after thorough examination of the wound, you find the slightest evidence of the peritoneal cavity having been invaded, do not hesitate a moment to make an exploratory laparotomy. Absolutely no other treatment is permissible.

How different this law is from the precepts of a few years ago! Even now there are many from whose brain the cobwebs have not been swept and who sit beside their patient with the sublimest faith in Nature, waiting for the signs of hæmorrhage or of peritonitis. Then the principle of immediate intervention was unthought of. Hesitancy was the watchword of the hour. It was considered folly to enlarge the wound, death to explore the abdomen. Large doses of opium were given and ice was liberally indulged in. Wise precepts for those times perhaps, but hardly applicable now. Do not wait for confirming symptoms; do not wait for peritonitis to develop. This class of cases gives the most brilliant results in surgery if common sense is but followed in their treatment. Take small abdominal wounds, for example. These are usually the result of a stab by a bayonet, sword, or dagger. The indication could not be stronger. There should be no hesitancy in urging immediate intervention. There is profuse hæmorrhage from the wound, or the escape of gas, intestinal contents, bile, or urine, or a portion of omentum or a segment of gut lies herniated in the wound. There may be painful distention if some hours have elapsed. But if the case is seen early, there may be practically no symptoms save the local ones. Do not wait for distention to supervene or the pulse to become weak. In the absence of all symptoms of grave injury, make an exploratory laparotomy at the earliest possible moment. In previous years it was perhaps right to delay in these cases, for the principles which were necessary to their successful treatment were not then perfected. But no such excuse will be accepted to-day. That some patients recover is no proof in this regard, for theirs were cases in which no grave visceral lesion or infection was present. The amount of infection is always more or less a matter for conjecture.

No abdominal wound is to be considered insignificant.

It is impossible to distinguish between insignificant wounds and grave ones in the first few hours following the infliction of the injury. The law of immediate intervention is imperative.

Proceed methodically. Enlarge the skin wound, then the fascial and muscular layers to the peritonæum. Before opening this widely, again disinfect carefully. Perhaps some discharge, such as urine, fæcal matter, or bile, will indicate the situation of the wounded viscus. If such discharge is present, proceed very carefully. Do not disturb the relationship of the exposed viscera until you have thoroughly examined them ocularly. Then raise the omentum and proceed very carefully. If this fails to develop any injury, and if fluid, blood, or fæcal matter, or gas—anything to indicate injury—is present, then partially eviscerate. Examine each organ carefully. Employ plenty of warm towels. Proceed methodically and, above all, gently. If from twenty-four to forty-eight hours have elapsed since the injury, be particularly careful how adhesions are disturbed. If multiple wounds of the abdominal wall are present, or if the nature of the injury leads one to expect multiple visceral lesion, the exploratory laparotomy should be made in the median line. This is particularly true in the case of stout people, whose thick abdominal walls make it difficult to retract the wound edges in lateral laparotomies.

PARAMYOCLONUS MULTIPLEX.*

By L. J. MORTON, M. D.,

BROOKLYN.

PARAMYOCLONUS MULTIPLEX, or convulsive spasm, convulsive tremor, or muscular spasm (taking the term in its literal translation), is a spasm of several muscles of the face, neck, arms, and lower limbs as well as of the muscles of the trunk. The muscles of the hands and feet are not involved. The spasms, which are clonic, are usually symmetrical and at times more violent than at others; the contractions vary in violence and frequency, the latter being anywhere from five to fifty a minute. The external muscles are the ones most frequently involved, *i. e.*, the deltoid, biceps, triceps, and quadriceps extensors, the flexors of the thigh, the gluteal, the peronei, or the gastrocnemii. This kind of tremor, with its shifting and varying forms of contraction, does not always render a diagnosis easy.

Friedreich, in 1868, was the first writer to fully describe and separate this disease from other forms of spasm so closely resembling it, *viz.*, hereditary chorea, electrical chorea, and saltatory spasm, or orchestra mania. Some writers tell us that the treatment of this disease, which they affirm is always successful, will assist us in making a diagnosis, but such has not been the happy experience of the writer, as one case in particular, which

will be mentioned later, ended in death a short time after its incipency, and in yet another case, which he will show you, the disease has existed for two years, but the patient is improving. In this latter case the differential diagnosis will be from another type of functional and organic nervous disorders. This disease is distinguished from chronic chorea inasmuch as in the muscle spasms, or myoclonus, the patient gives no history of hereditary or family taint, although the muscle movements and loss of inhibitory power resemble each other.

Electrical chorea is a disease of paludal origin, occurring in a country remote from ours. Our cases of myoclonus stand separate and alone. Saltatory spasm is a muscular clonic spasm of both lower limbs, and comes on when the patient attempts to stand or walk, giving a springing or involuntary jumping movement. This strange form of nervousness was first described by Bamberger in 1859. The spasm of myoclonus is more diffuse, involving muscles of the face, arms, and trunk as well as those of the lower limbs, and its character is not always clonic. It may be a quick tonic tremor or simply a slight quivering of the muscles, like flesh quivering, and may continue during sleep as well as in the waking moments, although the most violent forms of muscle spasms and choreic twitching absolutely cease during sleep.

The following case was seen by the writer in the practice of a neighboring physician: The patient, a man of about forty, was suffering from hæmorrhoids. He was advised to undergo an operation for their removal. He was physically strong—a vigorous and active laboring man of good habits. His kidneys were in a healthy condition and his heart's action was strong. The operation was quickly and skilfully performed, and the wound healed. After the operation he became depressed and frequently informed his friends that he did not think he would be well again, owing to the fact that he had been previously warned by his fellow-workmen that should he have any cutting operation performed upon him he would be very apt to die. This so preyed upon his mind that no persuasion on the part of his physician could relieve him from this impending dread, which in time proved only too true. On examination of the patient, a slight quivering of the muscles of the back was noticed, which developed into tonic and clonic spasms of all the muscles of the back of the trunk and lower limbs, especially of the glutæi and hamstring muscles. On removing the clothing and proceeding to examine the patient, these muscles were then seen in a violent convulsive spasm, but there was no loss of sensation in the muscles involved, and an examination of the parts operated upon showed nothing unusual. He had no difficulty in passing urine, and his bowels operated without the use of laxatives. He had premonitions of impending death and was sad and easily moved to tears. Treatment gave him scarcely any relief, and in about two weeks from the time of the operation he died. No autopsy was made, but a week before his death his heart became irregular and he suffered from insomnia and extreme restlessness during the day. Death was due to shock and exhaustion brought on by fright and worry.

It affords me great pleasure to present to you this

*Read before the Neurological Society of Brooklyn, May 23, 1901.

evening a case of paramyoclonus multiplex, a rare and interesting disease, in a young woman, twenty-six years of age, born in Ireland, but for the past ten years a resident of this city. Since her advent here she has worked hard as a domestic, and during a part of the time, besides performing her daily housework, at night nursed a sick brother, who subsequently died of pulmonary tuberculosis. Her twofold duties impaired her health very much, combined with the loss of her brother, to whom she was greatly attached. Within a few months of his demise a sister became ill of the same form of lung disease, and she attended her until she broke down and began to have these clonic spasms, which involved first the muscles of the right side of the body, viz., the muscles of the right arm and leg. The spasms then passed over to the muscles of the left arm and left leg, then to the muscles of the neck and lower face. For a time the muscle spasm in the legs was much greater than at present, and both limbs were feeble and she could not walk without assistance. Bear in mind that the nature of these spasms is purely clonic, and that they are more marked now in her arms than in any other part of her body. The patient and her attendant state that when she is alone and not observed the spasms are not so great as when she is trying to perform some task in the presence of observers. You see, all her limbs are twitching, and, on any effort to use her hands, the spasms become violent. You see, she is emotional, as is also her sister. I might add that this disease has existed for over a year and a half.

These cases are unusual, only a small number having been reported. Hammond has seen several and says that the disease is equally common in both sexes. This kind of tremor more closely resembles the following forms than any of the forms previously mentioned, *i. e.*, disseminated sclerosis, paralysis agitans, and myotonia congenita, and yet it is neither of these forms, because in this case we have no intention tremor, as the arm is not at rest when not used, as in disseminated sclerosis. Neither has she the staccato, or measured, speech which patients with disseminated sclerosis have. Again, in this case you do not see the fine fibrillary motions of the muscles of the fingers, or the pill-rolling motions of the forefinger and thumb, which are indicative of paralysis agitans; nor has she the peculiar gait known as festination. Paralysis agitans is a disease of advanced life, for, as a rule, the patients are above the fifty years' mark; this young woman is not twenty-six years of age.

Myotonia congenita is a disease (as its name implies) due to an hereditary taint, and runs through families, two or three children in the same family often having this disease. It was first described by Thomsen, of Schleswig, in 1876, and is known as Thomsen's disease, he himself having been a sufferer from it. The spasms are always tonic and involve the muscles of the fingers, arms, and face. It is a disease found in young children, and is readily recognized, for a blow with the percussion hammer throws the muscles into violent spasms lasting

several seconds; it is an incurable nervous disorder. In this patient's case before us, while she is far from being well, she is much improved, and the different reflexes, which were so highly exaggerated in the beginning, have now subsided, and she is much stronger than she has been at any time since her illness. Her condition was brought about by muscular over-exertion and mental worry. The prognosis, as a rule, is favorable, the patient making a good recovery after several months.

Treatment.—Tonics, rest, and fresh air are necessary, but in this individual case the prescribing of remedies has not been an easy task. She cannot tolerate cod-liver oil in any form, iron produces headache, strychnine causes intense irritability, and sodium bromide cannot be taken for any length of time, owing to its depressing effect on the heart. To overcome obstinate constipation, she takes a pill composed of aloin, compound extract of colocynth, and belladonna. I urge her to try to be cheerful and hopeful and avoid as much as possible all depressing influences. Galvanism and my favorite remedy for all ills, *i. e.*, living out of doors in the sunshine and drinking large quantities of good spring water, have proved very efficient in her case, and her appetite has improved. She eats with a relish three times a day and sleeps well at night, and, to use her own words, feels better as each day passes by.

A CASE OF CEREBELLAR APOPLEXY, WITH AUTOPSY.*

By LEONARD WEBER, M. D.,

NEW YORK.

ON September 10, 1900, I was called to see Mr. George H., a German, twenty-nine years old, single, salesman, living on the top floor of an old tenement on the west side of the city, among unsanitary surroundings. I found the man in bed, complaining of constant headache, front and back and top, constant dizziness, nausea, and vomiting, the latter increasing as soon as he raised his head or attempted to rise. With these symptoms he had been sick more or less for two months. The patient is a rather tall, pale, fairly well-built man with a scanty growth of hair and whiskers, his eyes dull and sunken deep in their sockets, face thin and pinched, skin clammy and cold, radial pulse full, throbbing, between 60 and 70 a minute. The systolic cardiac impulse could be both seen and felt in the normal place along the nipple line and also lower down, nearly as far as the scrobiculus, his abdomen was drawn decidedly in, with no tenderness anywhere, bowels constipated, urine of a specific gravity of 1.014 and showing a little albumin, more than a trace. The microscopical examination of the specimen sent the next day, as well as two subsequent ones, always showed a little albumin and a few hyaline and occasional epithelial and granular casts. There was no hereditary or acquired taint, no sign of syphilis, but the patient admits having had a gonorrhoea some years ago, from which he rapidly recovered, and further states that he has not

*Read before the New York Neurological Society, April 2, 1901.

been sick at all during the last two or three years, and has always been at his rather laborious business until he was taken with the above-mentioned symptoms, two months ago. These came on rather suddenly, and when he felt no better after two or three weeks of dispensary and home treatment he got himself admitted into a hospital, where he stayed two weeks and, feeling somewhat better, got his discharge and tried to go back to work. Though he was not much improved at that time, there was a period of remission of all original symptoms lasting about two weeks, but since September 1st he has not been able to leave his bed, his condition is wretched, and he cannot lift his head from the pillow without the occurrence of dizziness, nausea, and vomiting; the headache, present night and day, he feels pretty much all over the head, but more so in the back. He is perfectly sensible, sees, hears, and writes well, gives intelligent answers to all questions, and neither sensory nor motor disturbance of any kind can be made out. On taking him out of bed, he can stand and walk with his legs spread, and though exhibiting a slightly staggering gait, it is by no means the gait of a drunken man, but he begs most urgently to be put back to bed.

It was indeed not difficult at the first examination to exclude gastro-intestinal disease as the cause of the patient's illness, for all important symptoms pointed to a lesion in the central nervous system of a very grave character, such lesion probably located in the cerebellum; of the three pathological conditions to be thought of, tumor, hæmorrhage, or abscess in the cerebellar hemisphere, the first could be excluded on account of the absence of all pressure symptoms, etc.; the state of the urine, in conjunction with the hypertrophy of the left chamber of the heart, pointed to cerebellar apoplexy with considerable force, but in consideration of the rather lengthened period of the patient's illness an abscess might also be thought of.

Stating to the patient, and more pointedly so to his relatives, the grave character of his illness, I had him removed the next morning to St. Mark's Hospital. There, on examining him again from head to foot, no scars or discolorations on his skin were found, or any sensitive or tender spot about the thorax or abdomen. I might also mention that he had had neither cough nor expectoration. His abdomen was still more retracted than before, without tenderness, without hardness. All the cutaneous reflexes were increased, but there were neither pupillary nor retinal symptoms, nor other signs indicative of organic cerebral or spinal disease; what the patient vomited constituted a thin, watery liquid, sometimes yellow, more often yellowish-green to green. On being taken out of bed, he behaved the same as the day before, spreading his legs apart to steady himself, but he had not the staggering gait; all the three cardinal symptoms mentioned above became worse at once and unbearable. The presence of hæmorrhage would seem, after all, to be the correct diagnosis, though, on account of the period of eight or nine weeks having elapsed since the first symptoms of illness had set in, there might be progressive softening around the hæmorrhagic focus. The patient was given one sixth of a grain of morphine hypodermically and fed by rectal enemata, neither food nor drink being given by the mouth.

On the 14th the symptoms were rather worse all day long, and at 9 p. m. he fell asleep and slept for three hours; on waking, he complained again very much and expired suddenly at 2 a. m. on the 15th.

At the autopsy, which I made at 3 p. m. the same day, I found but slight rigor mortis, no suffusions or scars

or pigmentations. On opening the body, the entire venous system was found filled, almost gorged, with blood; lungs normal; heart about one third larger and longer than normal, the walls of its left chamber having double the normal thickness, the walls of the right chamber not notably increased in thickness, all the valves sound; the aorta, examined at its orifice and as far as its descending portion, showed an apparently normal intima, but its calibre was larger than normal. The stomach, the duodenum, and also the mucous membranes of both, though rather thin were otherwise quite normal. The entire colon was distended with gas. The liver and pancreas were apparently normal. Both kidneys were somewhat enlarged, reddish-brown in color, firm, embedded in their fatty involucrum. Their capsules proper could be stripped off without much trouble; the cortical substance was harder to cut than normal and was the seat of disseminated interstitial nephritis in the early stage. The cerebral membranes, the gray and white matter of the brain, the crura cerebri, the pons, and the medulla showed nothing abnormal. On removing the tentorium cerebelli, the right cerebellar hemisphere was noted to be a little more prominent than the left, and from a slight rent located about midway the blood seemed to have recently flowed down over the medulla toward the fourth ventricle, forming also a few fresh coagula compressing the part. In taking out the small brain and medulla with great care the small rent opened more and a large cavity was at once exposed in the substance of the hemisphere. It was filled with large, soft, and dark-red fresh coagula and some smaller ones of older date. The commencement of the formation of a smooth wall around the cavity was distinctly noted; the left hemisphere and the vermicular body were found to be normal.

Cerebral apoplexy, induced by marked hypertrophy of the left chamber of the heart, with and without renal disease, is not of very rare occurrence, but the seat of the apoplexy and the clinical features of this case, in conjunction with the proofs obtained at the autopsy, are of sufficient interest to have the case placed on record.

25 WEST FORTY-SIXTH STREET.

Correspondence.

LETTER FROM BUFFALO.

The Pan-American Exposition.—The Emergency Hospital.—The Medical Staff.—The Infant Incubators.—The New York State Medical Association's Meeting.—A Strange Case of Double Consciousness.

BUFFALO, June 1, 1901.

THE PAN-AMERICAN EXPOSITION is open, that is all, for it is so far very incomplete. Nothing is ready. The booths in the Exposition buildings proper are not by any means nearly all occupied, only three or four of the State buildings at this time of writing are open, and even the construction of the majority is far from completed. The "streets" of the Exposition are, with few exceptions, not paved, and on rainy days, and there have been over ten consecutive ones, are ankle-deep in mud. The decoration of even the completed portions of the buildings is still in

progress. It seems as though it would be some weeks before the Exposition could be properly declared "at home to callers."

This is not the place, however, to descant upon the Exposition as an Exposition; suffice it to say that for excellence of design, beauty of color (for the buildings, unlike those of the preceding Expositions, are all to be chromatically adorned), and general æsthetics, it bids fair, when ultimately finished, to be second to none.

Of great interest to medical visitors will naturally be the Emergency Hospital at the West Amherst Gate. The hospital staff has been at work on a temporary basis since August last, when the construction began, but the new building has only been occupied during May. It is admirably designed and contains, besides operating and dressing rooms, pharmacy, offices, quarters, etc., about thirty beds. The beds stand higher from the ground than is usual, which is a source of great relief to a dresser, too often subjected to the penalty of a backache from bending for hours over a succession of patients. One bed on exhibition there is very ingenious. It consists of a canvas sheet stretched on a movable frame, and perforated for the use of a bedpan. Ordinarily, this canvas sheet lies in close contact upon the mattress. When required, a mechanical arrangement elevates the frame, canvas and all, bearing the patient, who is thus not compelled to be moved, and the bedpan is inserted between the raised canvas stretcher and the mattress. A mechanical arrangement at the foot, with the aid of this canvas, further allows the formation of an inclined plane with a minimum of disturbance.

Upward of 1,100 cases have been attended to by the hospital staff since August. Most of them, of course, have been minor accidents, but there have been also electric burns, fractures, and a few temporary medical cases. In any emergency, medical or surgical, that may occur on the grounds, the patient is promptly conveyed by ambulance to the hospital and receives attention according to the nature and gravity of the case; those that are likely to prove long cases are distributed by turns to the various hospitals of Buffalo, in due course.

The medical staff is as follows: Medical director, Dr. Roswell Park; deputy medical director, Dr. Kenerson; sanitary inspector, Dr. Wilson; internes, Dr. A. Zittel, Dr. Alexander Allen, and Dr. Edward Mann; matron, Miss Walters.

One interesting event was the birth of an Indian papoose in the grounds, at which one of the internes was present. The patient squatted on the ground in an upright position, while a squaw, standing behind, kept up an intermittent compression on the uterus in front. On examination, the interne found the os fully dilated. A few moments later, a single pain resulted in the expulsion of the child. In the present instance, some little difficulty, due to placental adhesion, occurred, which was dealt with by the interne. The next day, he saw the woman about, engaged upon her ordinary occupations.

An intensely interesting exhibit to physicians is the infant incubators. These are situated in a most carefully constructed and complete building near the Service building and Emergency Hospital, at the West Amherst entrance. The crudeness of the methods of attempting to rear premature or weakly infants, by wrapping them in wadding, sheepskin, or feathers, or by keeping the cot close by the fire, impelled Dr. Credé, some sixty years ago, to the invention of an incubator consisting of a metallic box with double sides, through which hot water was caused to flow. Dr. Tarnier, of Paris, in 1878, conceived the idea from the incubators for poultry installed by M. Odille Martin, at the *Jardin d'Acclimation*, at Paris, of applying similar apparatus to the rearing of prematurely born children, and the first incubators on this principle were used in the Paris Maternity Hospital in 1880. The results proved satisfactory, and led to the formation of a private institution in Berlin for the preservation of these unfortunate infants. Its success was great, and many healthy and fully developed children, both mentally and physically, now meet in annual reunion to give indisputable testimony to the fact. In 1897, a public exposition of the system was given in London, and the entries in the visitors' book, among which we noticed the names of such representative obstetricians as Clement Godson and others, amply testify to the satisfaction it aroused. Since that date, a permanent institution of the kind has existed successfully in London.

American physicians have now the opportunity of examining its working for themselves. Briefly, the construction is as follows: The incubator is a glass case in a metal frame, supported on metal legs. In it is suspended a cot of woven wire, adequately padded. Fresh air is admitted by a large tube from outside the room. This air, first passing through an antiseptic fluid and being filtered through cotton, enters at the bottom of the case and strikes an umbrella-like shield below the cot, and is thus deflected downward till it meets the warm current of air provided by a Bunsen's burner placed outside the case. Inside the incubator is a thermostat, which, by its contraction and expansion, automatically works a lever outside, lowering or raising a cover on the burner, and thus directing more heat inside the incubator, or letting it escape outside, according as the inner temperature falls below, or rises above, the required degree. A thermometer in front registers the degree existing. The foul air escapes from above through an air shaft. In a large sanitary room, well lighted, stand about a dozen of these incubators, occupied by premature or weakly infants, swathed in German fashion. These infants are sent by the local physicians, and handed over to the care of the institution. They are weighed, properly clothed, and placed in the incubator. They are generally under five pounds in weight on admission. A staff of wet nurses is kept on the establishment, all of them being medically examined and carefully selected. They live in the building and their diet and regimen are carefully regulated.

The infants are taken out of the incubator every two hours to be suckled, a trained nurse sitting by, to see that the child actually receives nourishment, and is not merely fruitlessly "put to the breast." Those that are too weakly to exercise suction are fed with the Gavage spoon until they become robust enough to feed themselves. At the back of the incubator room is a model nursery, where all that forms part of sanitary toilet for the infants is performed. A miniature elevator takes the infants to the upstairs quarters to be fed during the night. Here the nurses, the wet nurses, and the medical directors, Dr. Schenkheim and Dr. Coney, live. The temperature is kept equable throughout the entire building at a degree comfortable for adults, without oppressiveness, while in the incubators the little patients can have any required temperature all to themselves.

It is stated that out of the very large numbers of premature and weakly children that have been submitted to this artificial rearing, upwards of eighty-five per cent. have been saved, as compared with the normal 25 to 30 per cent. under ordinary conditions. The success of this method in Germany, France, and England should certainly lead American physicians to take this opportunity of studying it for themselves.

The New York State Medical Association held its seventeenth annual meeting here on May 31st, and had an attendance of about one hundred. Dr. William H. Thornton presided. At the morning meeting, the Mayor gave an address of welcome. The president, Dr. John A. Wyeth, and the secretary, Dr. Frederick Holme Wiggin, then addressed the meeting, and explained that as the association had now acquired a charter, a reorganization of all the branches, which, however, was a mere formality, was rendered necessary. In the afternoon the election of officers took place with the following result: President, Dr. Charles A. Wall, of Buffalo; vice-president, Dr. James W. Morris, of Jamestown; secretary, Dr. Bernard Cohen, of Buffalo; treasurer, Dr. W. Irving Thornton, of Buffalo. The members of the nominating committee of the State association are Dr. J. Z. Lusk, of Warsaw, and Dr. A. G. Bennett, of Buffalo. The next annual meeting is to take place on July 1, 1902, at Chautauqua. In the evening a dinner was given at the Buffalo Club. A special train is to carry the members, on June 3d, to St. Paul for the meeting of the American Medical Association.

Buffalo has had a strange case of double consciousness. A young man came to Buffalo on the evening of May 24th and took a room on Chippewa Street. On May 26th he approached the minister of the North Presbyterian Church, after evening service, and explained his condition, saying that he had forgotten who he was, where he came from, etc.

The superintendent of police was communicated with, and the police surgeon was summoned. In answer to the questions of the latter the young man was unable to say what his name was, where he lived, whether he was

married, or indeed anything at all. He seemed to remember, however, most of what had occurred to him subsequently to his arrival in Buffalo. He was then returned to the police station. He made no objection to being searched, but nothing found revealed his name. The address of a married woman was found, however, but he denied any knowledge of who she was. Dr. William C. Krauss, Dr. Floyd S. Crego, and Dr. James W. Putnam were then summoned, and it was ultimately decided to hypnotize him, which was easily effected. When under the influence, he readily answered questions as to his identity, and informed the doctors that he came from Providence, was twenty-five years old, married, and the representative of an insurance company. He did not know that he was in Buffalo, and was bewildered as to how he got there. On being restored to full consciousness, he remembered deciding to come to the Exposition, but everything that had transpired subsequently appeared now to be a blank to him. He was then questioned as to the identity of the woman whose address had been found on him. He seemed surprised that it should be known, but answered readily that she was his married sister. She was then telegraphed to, and thus a mystery was cleared up.

Therapeutical Notes.

To Sweeten the Breath.—The *New York State Journal of Medicine* for June gives the following:

R Salicylic acid, } of each...15 grains;
Sodium bicarbonate, }
Rectified spirit. 1 drachm;
Spirit of peppermint. 10 drops.

M.

A teaspoonful in a small cupful of hot water, to be used as a mouth wash.

The Ammoniacal Blister.—The process of blistering with ammonia, which is very rapid, is thus described in the *Agenda-médical* for 1901: Pour from eight to ten drops of very strong ammonia water into a shallow watch-glass, cover the liquid with a piece of linen a little smaller than the glass, and apply to the skin. Sometimes a coin is used instead of the watch-glass.

Diuretic Wine of Squill.—According to the *Agenda-médical* for 1901, the *vinum scilliticum amarum* of the Charité Hospital is made after this formula:

R Aselepias root.	15 parts;
Angelica root.	15 "
Dried squill.	15 "
Huanuco cinchona bark.	60 "
Lemon peel.	60 "
Winter's bark.	6 "
Absinthium leaves.	30 "
Melissa.	30 "
Juniper berries.	15 "
Mace.	15 "
Alcohol (60°).	200 "
White wine.	4,000 "

Macerate for ten days, and filter. The dose is three ounces, to be taken once only, in the morning.

For Tuberculous Laryngitis.—The *New York State Journal of Medicine* for April says that in the later stages of tuberculous laryngitis the following insufflation for the relief of pain, which is usually severe, and the restoration of the voice, may be given:

- R̄ Iodoform. 2 drachms;
- Cocaine hydrochlorate. 1½ grains;
- Morphine hydrochlorate. ½ a grain.

M.

A small amount to be insufflated by the patient with a bent glass tube, to relieve the pain.

Amyl Nitrite as a Remedy for Seasickness.—Martindale and Westcott (*Extra Pharmacopœia*, 1901) give a formula which amounts to the following:

- R̄ Amyl nitrite. 2 parts;
- Alcohol (90 per cent.) 16 “
- Powdered tragacanth. 1 part;
- Distilled water, enough to make. 240 parts.

Mix the amyl nitrite and the alcohol and add them to the tragacanth (contained in a dry phial), then add the water gradually and shake well. The dose is from one to two drachms. The frequency of its repetition is not specified.

Robin's Syrup of Glycerophosphates.—Martindale and Westcott (*Extra Pharmacopœia*, 1901) quote the following formula from the *Bulletin général de thérapeutique*:

- R̄ Calcium glycerophosphate. 6 parts;
- Sodium glycerophosphate. 2 “
- Potassium glycerophosphate. 2 “
- Magnesium glycerophosphate. 2 “
- Iron glycerophosphate. 1 part;
- Tincture of ignatia amara. 2 parts;
- Pepsin. 3 “
- Diastase. 1 part;
- Tincture of kola. 10 parts;
- Syrup of cherries, enough to make
(by weight). 200 “

M.

From 1 to 4 drachms may be taken with each meal.

Catheter Oil.—Martindale and Westcott, in the tenth edition of their *Extra Pharmacopœia* (London, 1901), give the following formula:

- R̄ Phenol. 1 part;
- Castor oil. 7 parts;
- Almond oil. 8 “

M.

They add the following as the formula of the *oleum lubricans* employed in St. George's Hospital:

- R̄ Cocaine. 25 grains;
- Oil of eucalyptus. 10 minims;
- Castor oil, } each. ½ ounce.
- Olive oil, }

M.

Cold and Heat in Treatment of Sprains.—Dr. J. W. Wainwright (*Syllabus of New Remedies and Therapeutic Measures*, Chicago, 1901) remarks that the modern treatment of sprains with cold and heat is so satisfactory and the theories for their employment are so rational that no better example can be chosen to illustrate their indications as therapeutic agents. The first acute inflammation is combated with an ice-bag. This, says the author, causes contraction of the blood-vessels, with im-

mediate diminution of the supply of blood to the part, besides a decrease in the exudation and diapedesis, at the same time exerting some anæsthetic effect. When the acute inflammation has subsided, in the course of a few hours if the bag has been diligently refilled, there is more or less exudate in the tissues, causing stiffness, pain on motion, etc. Then dry hot air, at as high a temperature as from 250° to 400° F., will be found the best means of stimulating both the blood-vessels and the lymphatics and so hastening the dissolution and absorption of the products of the previous inflammation.

Calcium Chloride as a Hæmostatic.—M. Mathieu (*Nouveaux Remèdes*, April 24th), at a recent meeting of the Société de thérapeutique, recommended calcium chloride in daily quantities of forty-five grains, in many divided doses, administered in an aromatic water or in milk, in the intestinal hæmorrhages of typhoid. He had found this remedy of particular service in a recent epidemic. At the same time he practised extensive intestinal lavage to remove the blood that inundated the intestine and had a tendency to remain there.

At the same meeting M. Robin extolled the value of calcium chloride in hæmoptysis. The best daily dose was a drachm, divided, of course, but he recommended its administration in conjunction with some preparation of opium, in consequence of the liability of the drug to irritate the stomach, from its caustic nature.

The Treatment of Menorrhagia.—M. Lafond-Grelletz (*Gazette hebdomadaire des sciences médicales de Bordeaux*, March 17th; *Gazette hebdomadaire de médecine et de chirurgie*, April 28th) says that M. Dalché recommends ergotin after the following formula:

- R̄ Ergotin. 1½ grains;
- Quinine sulphate. ¼d of a grain;
- Powdered digitalis. ⅙th of a grain;
- Powdered coca. q. s. for one pill.

From four to five to be taken daily.

While this formula is good, M. Lafond-Grelletz considers that possibly the tonics have as much to do with the result as the ergotin. When the menses are regularly profuse, M. Lafond-Grelletz employs calcium chloride, whose hæmostatic action has been demonstrated by Cornil and his pupils, Wright, P. Carnot, and Trémolières, etc. The following formula is given:

- R̄ Calcium chloride. 135 grains;
- Syrup. 15 drachms;
- Water. 45 “

M.

One or two tablespoonfuls daily. But, in the subjects of Bright's disease, calcium chloride is liable to determine toxic accidents, vomiting, and headache, and should therefore be avoided wherever there is reason to suspect nephritis. In this case it is best to substitute the use of a ten-per-cent. preparation of gelatin, from five to ten cubic centimetres being injected daily.

In general—1. Calcium chloride, acting as a hæmostatic, both locally and on the volume of the blood, diminishes the amount of loss during the periods, and these become regularly normal after a prolonged treatment. 2. In spite of its vascular action, which is always marked, it cannot be efficaciously employed for dysmenorrhœa, since it restrains neither the duration nor the intensity of the pain. 3. Its action is contraindicated in all persons with renal disease.

THE NEW YORK MEDICAL JOURNAL,
62-68 West Broadway.

NEW YORK, SATURDAY, JUNE 15, 1901.

THE ST. PAUL MEETING.

THE fifty-second annual meeting of the American Medical Association, held in St. Paul last week, was memorable from more than one point of view. Those of our readers who were not present will have deduced this from the president's address and from the action taken on the plan of reorganization. The reorganization, tantamount to a new constitution, will, as we have before remarked, make the general sessions far more amenable than before to parliamentary rules of procedure and better able to arrive speedily at a correct understanding of the merits of such questions as may come before the association. Many of the men who most thoroughly recognized all this before the meeting were fearful that, nevertheless, the scheme would fail of adoption this year, although sure to be sanctioned eventually. The result shows once more that we should never despair of a good cause.

The choice of a New York man as president for the ensuing year and of a place in the State of New York for holding the next meeting may doubtless be taken to foreshadow the reestablishment of the most cordial relations between the national body and the profession of the State. Now that the presidency has been conferred upon one of their number, the physicians of the State of New York should make no distinction in their own minds as to whether he represents the old or the new State organization, for it is certain that no thought of discrimination on that score governed the nominating committee. It is to be hoped, indeed, that there will soon be no factions, and that the two State organizations will be blended into one.

The next meeting will be comfortably bestowed, for the capacity of the Saratoga hotels is very great. But the entertainment of the members is to be thought of as

well as their lodging. This the profession of the whole State must take upon itself. It would be wrong to leave the burden to be borne by Saratoga alone after the superb hospitality of the twin cities of St. Paul and Minneapolis. We think we can promise our colleagues in all parts of the country such an effort as the State of New York can make to approach the standard of that hospitality.

IS THERE A SPECIFIC GLANDULAR FEVER?

FOUR or five years ago the subject of so-called "glandular fever" was considered at a meeting of the New York Academy of Medicine. But few of those who received the announcement cards had any well-defined idea of what was meant by the term, although there were some who remembered that in 1889 Pfeiffer, of Wiesbaden, had applied it to a febrile condition accompanied by swelling of certain lymphatic glands, chiefly those of the neck. What little acceptance as an entity the disease met with seems to have been due to its prevalence among children and to the fact that the glandular swellings, sometimes ending in suppuration, were not traced to any of the recognized causes of lymphadenitis. This slight basis for accepting "glandular fever" as a disease *sui generis* seems to have been reduced to the vanishing point by two recent French articles, the one, by M. Marcel Labbé, published in the *Presse médicale* for April 17th, and the other, by M. Guinon, which we find in the May number of the *Revue mensuelle des maladies de l'enfance*.

M. Labbé calls "glandular fever" *la prétendue fièvre ganglionnaire*, and M. Guinon agrees with him thoroughly. The latter thus describes the affection: The attack is sudden, with rather sharp fever which may reach a temperature of from 102° to 104° F. The only local abnormality noticeable at first, and that in but few cases, is moderate reddening of the pharyngeal mucous membrane. At the end of two or three days, sometimes sooner, there is painful swelling of the glands at the angle of the jaw on one side; they are hard, tender, and of impaired mobility, and occasionally they show a tendency to run together. In some cases the swelling is limited to the group of glands at first affected; in others it extends to those of the neck. In some instances the skin becomes red, but suppuration is rare; nevertheless, there may remain an indolent swelling for ten days or two or three weeks. Pfeiffer even observed an extension of the disease to the glands of the thorax, as was manifested by a spasmodic cough, and to those of the mesen-

ry, giving rise to abdominal pain and diarrhœa. In addition to the typical cases, very different ones are noted, such as those of infectious nephritis.

Now, asks M. Guinon, what is there specific in all this? Adenopathies are frequent in children, and it is the glands of the neck that are generally involved, owing to the frequency of lesions in the neighboring buccal, nasal, and pharyngeal mucous membranes. These lesions are not always discoverable, but they may still exist. When they are discovered, they often seem insignificant, but here as elsewhere in the body, in the glands of the axilla and in those of the groin, lesions that appear trivial and even those that are undiscoverable do give rise to well-marked changes in the neighboring lymphatic glands. It may well be that in such cases the glandular inflammation is the cause of the fever, but the causes of the ganglionic affection are diverse; consequently there is no such thing as a specific glandular fever. In other words, as M. Guinon puts it, there may be a glandular fever, but there is not *the* glandular fever.

THE HÆMOLYMPH GLANDS.

RATHER more than twenty years ago Lankester used the term hæmolymp as a collective name for the red and white blood-corpuscles and the lymph-corpuscles. At that time there have been discovered certain glands, distinguishable, although with difficulty, from ordinary lymphatic glands by their containing blood corpuscles as well as lymph sinuses. These glands appear to take part in the elaboration of both the blood and the lymph, and they are called hæmolymp, or hæmal glands. They have recently been made the subject of special study by Dr. Aldred Scott Warthin, assistant professor in pathology in the University of Michigan, who has published an interesting account of them in the *Journal of the Boston Society of Medical Sciences* for April 23d.

These glands, according to Dr. Warthin, are of two distinct types, called by him, respectively, splenolymp glands and marrow lymph glands, but between the two typical forms, he remarks, there is every possible transition form. The splenolymp glands are the more frequent of the two varieties. In some instances their tissue so resembles that of the spleen that they may be regarded as accessory spleens. As a rule, they are softer than ordinary lymphatic glands, but frequently they cannot be distinguished from them macroscopically. The lymphadenoid tissue lies between trabeculæ that run

into the gland from a very thick capsule of fibrous connective tissue. Immediately beneath this capsule there is a small blood sinus, branches of which accompany the trabeculæ, increasing in size toward the centre of the gland. The tissue between the sinuses resembles that of an ordinary lymphatic gland. The chief function of these glands appears to be that of hæmatolysis, and in the active glands the destruction of the red cells takes place to an extent far exceeding that in the spleen. The glands produce leucocytes, but they do not appear to elaborate red corpuscles. They are found principally in the neighborhood of the solar plexus and about the adrenal and renal vessels, occasionally also in the omentum, the mesentery, and the epiploica, as well as in the thymus and thyroid regions.

The marrow lymph glands are of less frequent occurrence, and Dr. Warthin has found them only in the retroperitoneal region, always close to the large vessels, almost invariably behind the aorta or between it and the vena cava. They are flattened and very long and always lie parallel to the neighboring vessel. They are very soft and of a white or pinkish color. Under ordinary conditions the function of these glands is not so clear as that of the splenolymp glands, but they are evidently leucocyte-forming organs, and under certain pathological conditions they form red blood-cells. They become atrophied in old age. They occasionally contain cells of the type of bone-marrow giant cells, and it is suggested that in certain morbid conditions they may have a function compensatory for that of the marrow.

Like ordinary lymphatic glands, these hæmolymp glands show pathological changes in cases of inflammation, congestion, carcinomatous metastases, tuberculous disease, etc., and in a limited number of instances of pyæmia, various forms of anæmia, and leucæmia they have been found to show changes that must be looked upon as specific in character.

THE FIGHT AGAINST MOSQUITOES.

THE average young person probably harbors a hazy notion that whatever is good for his health is disagreeable. There are many instances, however, in which health and comfort are promoted by the same means. One of them, as we have only lately learned, is the prevention of mosquito-bites, and, in our opinion, the Division of Entomology of the United States Department of Agriculture has done the people a distinct benefit by issuing a circular (No. 13, second series) concerning mosquitoes and fleas. While the entomologist whose signa-

ture is appended to the circular, Mr. L. O. Howard, recognizes that the thorough screening of windows and the use of the bed net are the best means to employ against the access of mosquitoes in dwellings, he makes some very practical and useful suggestions as to the destruction of those mosquitoes which, in spite of these measures, do inflict their bites even in the best-regulated families. As some of the defensive means suggested may not be generally known, we will mention them briefly. The slow burning of cones made of moistened pyrethrum powder gives great relief from the attacks of mosquitoes in a room, but does not kill the insects, and is only a palliative. Mosquitoes found on the ceiling of a bedroom may be killed easily and quickly by placing under them a shallow tin vessel nailed to the end of a stick and moistened on the inside with kerosene. But the most satisfactory means of fighting mosquitoes is to destroy their larvæ or abolish their breeding-places by draining ponds and marshes, by stocking pools with fish, and by the use of kerosene on the surface of the water. Approximately, an ounce of the oil to every fifteen square feet of surface is sufficient, and generally the application need be made only once a month. Mr. Howard doubts, however, if it will prove feasible to treat extensive salt marshes in this way. Cesspools, cisterns, etc., should be treated in the same manner. If drinking-water is drawn from the bottom of a tank, as is commonly the case, there is no objection to coating the surface of the water with kerosene. In the matter of tanks, cisterns, cesspools, etc., there should be concerted action in a district, for a family may suffer from their neighbor's mosquitoes.

OUR SUBSCRIBERS' DISCUSSIONS.

THE time allowed for manuscripts sent in competition for the first prize, on the question "What is the best treatment of the stump of the umbilical cord?" expired on Monday, the 10th inst. We have received numerous answers, and several of them are well worthy of publication. The task of reading all that have been received and passing upon their merits will necessarily occupy some time, but we expect to accomplish it in time to announce the award in our next issue. Meantime we would remind our subscribers that the time for receiving answers to the second question will expire on July 10th. We would say to them also that we should be glad to receive suggestions from them as to topics for subsequent competitions.

THE PRICKING OF THE "UREINE" BUBBLE.

IN our issue for May 18th we gave Dr. Walter S. Haines and Dr. Charles S. Woods, of Chicago, credit for having shown the fallacy of the supposed discovery of an essential constituent of the urine termed "ureine." We have since been informed that A. F. Chace, B. S., A. B., and William J. Gies, Ph. D., of the Department of

Physiological Chemistry of the College of Physicians and Surgeons, Columbia University, New York, was the first to make and publish (*Medical Record*, March 2) this demonstration, quite a month prior to the appearance of the article by Dr. Haines and Dr. Woods. It therefore, is entitled to the credit of priority.

THE DETERMINATION OF DEATH BY X-RAYS.

THE subject of the definite determination of death is one of great importance, and new tests are from time to time submitted. The latest one suggested, as we learn from the *American X-Ray Journal* for April, which quotes the passage without, however, stating its authority, is that of Professor Ottolenghi, of the University of Siena. The professor is said to have "discovered" that while it is easy to apply the rays to the lungs of a person who is alive or in trance, it is extremely difficult, indeed practically impossible, to apply them to the lungs of a person actually dead." The reason is that some intervening obstacle prevents the rays from penetrating into the body. He has repeatedly made a test of this kind always with the same result. Professor Ottolenghi therefore suggests that, as this test can easily be made by any physician, it should in future be employed in cases where there exists doubt of death.

It seems to us that the value of this test could be easily settled by experiment and that its further investigation is desirable.

A NEW PSYCHOLOGICAL JOURNAL.

WE have received the first number, for June, of the *Journal of Mental Pathology*, a large octavo of sixty-four pages, edited by Louise G. Robinovitch, B. ès L. M., and published in New York. The numbers are to be issued monthly, except in the months of August and September. The editorial board consists of Dr. V. Magnan, Dr. A. Joffroy, and Dr. F. Raymond, of Paris; Charles K. Mills, of Philadelphia; Dr. J. Morel, of Belgium; Dr. C. H. Hughes, of St. Louis, and Dr. E. Reclus, of Bordeaux, and on the title-page there is a long list of contributors. The new journal presents a fine appearance, and its contents are of unquestionable value.

THE LIBRARY OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS.

WE learn that this library, housed for the past year in its handsome new building in Bedford Avenue, Brooklyn, embraces over 30,000 volumes, 15,000 pamphlets, and some 500 current medical periodicals. The society is appealing for contributions to a permanent library endowment fund and for gifts of medical books, journals, transactions, etc. We hope it will succeed in adding largely to its resources, and we believe that it will, for the professional brethren who live in Brooklyn are noted for their public spirit.

News Items.

Society Meetings for the Coming Week:

MONDAY, June 17th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society.

TUESDAY, June 18th: New York Academy of Medicine (Section in General Medicine); Buffalo Academy of Medicine (Section in Pathology); Ogdensburgh, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Society of the County of Kings, N. Y.; Baltimore Academy of Medicine.

WEDNESDAY, June 19th: Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York private; New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, June 20th: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Massachusetts, Society for Medical Improvement (private); Medical Society of City Hospital Alumni, St. Louis; Atlanta Society of Medicine.

FRIDAY, June 21st: New York Academy of Medicine (Section in Orthopaedic Surgery); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society; Chicago Gynecological Society.

SATURDAY, June 22d: New York Medical and Surgical Society (private).

Marine-Hospital Service Health Reports:

The following cases of smallpox, yellow fever, and plague were reported to the surgeon-general during the week ending June 1, 1901:

Smallpox—United States and Insular.

Table listing smallpox cases in the United States and Insular regions, including locations like San Francisco, Chicago, and New York, with dates and case counts.

Smallpox—Foreign.

Table listing smallpox cases in foreign countries, including locations like Vienna, Rio de Janeiro, and Bombay, with dates and case counts.

Table listing smallpox cases in Europe and South America, including Warsaw, Malaga, and Valancia, with dates and case counts.

Yellow Fever.

Table listing yellow fever cases in Rio de Janeiro, Panama, and Havana, with dates and case counts.

Plague—Insular.

Table listing plague cases in Cebu and Manila, Philippines, with dates and case counts.

Plague—Foreign.

Table listing plague cases in Formosa and Basra, with dates and case counts.

The following cases of smallpox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending June 8, 1901:

Smallpox—United States.

Table listing smallpox cases in the United States, including Los Angeles, San Francisco, and Chicago, with dates and case counts.

Smallpox—Foreign.

Table listing smallpox cases in foreign countries, including Buenos Ayres, Prague, and London, with dates and case counts.

Yellow Fever.

Table listing yellow fever cases in Liberia, Costa Rica, with dates and case counts.

Cholera.

Table listing cholera cases in Bombay, Calcutta, and Madras, India, with dates and case counts.

Plague.

Table listing plague cases in Cape Town, Bombay, Calcutta, and Karachi, with dates and case counts.

Infectious Diseases in New York:

We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending June 8, 1901:

DISEASES.	Week end'g June 1		Week end'g June 8	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	25	2	30	5
Scarlet Fever.....	505	38	449	30
Cerebro-spinal meningitis	0	4	0	0
Measles.....	329	11	302	13
Diphtheria and croup...	247	50	241	48
Small-pox.....	64	17	86	16
Tuberculosis.....	286	158	226	152

Naval Intelligence:

Official List of Changes in the Medical Corps of the United States Navy for the Three Weeks ending June 8, 1901:

- ARMSTRONG, E. V., Passed Assistant Surgeon. Detached from the *Vermont* and ordered to the Key West Naval Station for duty at Dry Tortugas.
- BRISTER, J. M., Assistant Surgeon. Detached from the *Independence* and ordered to the Asiatic Station via the *Hancock*.
- CORDERIO, F. J. B., Surgeon. Detached from the *Buffalo* and ordered home to await orders.
- COSTIGAN, J. F., Passed Assistant Surgeon. Detached from the *Yorktown* and ordered home. His resignation to be accepted after his arrival.
- GARTON, W. M., Assistant Surgeon. Detached from the Washington Navy Yard, June 1st, and ordered to the *Indiana*.
- HAAS, H. H., Assistant Surgeon. Detached from the Naval Hospital, New York, and ordered to the Norfolk Navy Yard.
- IDEN, J. H., Assistant Surgeon. Ordered to duty at the Naval Hospital, Chelsea, Massachusetts.
- LIPPITT, T. M., Assistant Surgeon. Ordered to the Washington Navy Yard, June 1st.
- MCCLANAHAN, R. K., Assistant Surgeon. Ordered to the *Culgoa*.
- PLUMMER, R. W., Assistant Surgeon. Detached from the *Nashville* and ordered to the *Princeton*.
- RICHARDSON, R. R., Assistant Surgeon. Ordered to the Naval Hospital, New York.
- SHIFFERT, H. O., Assistant Surgeon. Ordered to the *Nashville*.
- THOMPSON, E., Assistant Surgeon. Detached from the *Petrel* and ordered to the *Solace*.
- WILLIAMS, R. B., Assistant Surgeon. Detached from Dry Tortugas and ordered home to be ready for sea duty.

Army Intelligence:

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department of the United States Army from May 25 to June 8, 1901:

- ALEN, IRA A., Captain and Assistant Surgeon. The leave of absence granted him is extended five days.
- CHAMBERLAIN, WESTON P., First Lieutenant and Assistant Surgeon. The leave of absence granted him is extended twenty-three days.
- COLLINS, CHRISTOPHER C., First Lieutenant and Assistant Surgeon, will proceed to Fort Bayard, N. M., for duty.
- DOUGHERTY, JAMES C., Contract Surgeon, will proceed to Aibonito, Porto Rico, for duty, to relieve HARRY A. EBERLE, Contract Surgeon.
- HARTSOCK, F. M., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month.
- KENDALL, WILLIAM P., Major and Surgeon, is granted leave of absence for fourteen days.
- WARD, JOSIAH M., Acting Assistant Surgeon, having returned to duty, will return to his station, Carranglan, Province of Nueva Ecija.
- WYETH, MARLBOROUGH C., Major and Surgeon, is granted leave of absence for three months.

Scarlet Fever.—An epidemic of scarlet fever is reported from Amsterdam, near La Crosse, Wis.

Typhoid.—Typhoid is reported to be raging with some virulence at Pittsburgh and certain districts of Philadelphia.

Foreign News Notes.—According to cable dispatches, the Sultan of Turkey intends to present to the Berlin Hospital a wing, the plans of which have been sent to Emperor William for approval.

Appointment of Physician-in-General to the Brooklyn Post-office.—Dr. W. H. Clowminzer has been appointed physician-in-general to the Brooklyn post-office department, at a salary of \$1,200 a year, to take office July 1st.

An American Woman Appointed Superintendent of Nurses in a Paris Hospital.—Miss Marie Louise Meier, a nurse at the Grady Hospital, Atlanta, Ga., has been appointed superintendent of nurses in the Hospital Larneau du Chantel, in Paris. She will leave Atlanta to assume the duties of her new position in December.

Consumptive Immigrants not Admitted to the Country.—The order of the superintendent of immigration, received by the commissioner of immigration for New York, that tuberculosis of the lungs is to be considered a dangerous contagious disease, is expected to result in a large decrease in the number of immigrants admitted to this country. Heretofore immigrants having tuberculosis of the lungs have been admitted unless the disease was in an advanced stage.

Assistant Army Surgeons Honorably Discharged.—By direction of the President, the following named assistant surgeons of the army have been honorably discharged as majors and surgeons in the volunteer army only, to take effect on June 30th: Captain H. C. Fisher, Captain E. L. Swift, Captain John S. Kulp, Captain I. P. Reynolds, Captain M. W. Ireland, Captain William F. Lewis, Captain Paul Chillock, Captain A. N. Starbuck, Captain P. C. Fauntleroy, Captain Charles Willecox, and Captain Henry A. Shaw, and First Lieutenant George W. Mathews.

Work of the Milk Commission of the Medical Society.—The chairman of the commission of the Medical Society of the County of New York reported on June 10th to the society on milk conditions in New York. A year ago the society appointed the commission to inspect the milk supply. After a full investigation of existing conditions, the commission is now prepared to certify that milk of any dealer whose product comes up to its standard. Two dealers have already fulfilled the condition laid down, and others will follow their example. "This is the first step in the improvement of the milk supply in this city," said the chairman. "If the public will only second the work of the commission, pure milk will be here long before long as common as impure milk is at present. To obtain a guarantee from the society's commission the dealer must prove, for one thing, that the acidity of the milk he wishes to sell is not higher than two per cent."

Dr. Remsen Elected President of the Johns Hopkins University.—At a meeting of the trustees of Johns Hopkins University, recently held at Baltimore, Md., Dr. Remsen, Ph. D., LL. D., professor of chemistry in Johns Hopkins University since 1876, was elected president of the university, succeeding Dr. Daniel C. Gilman, who resigned. Dr. Remsen is fifty-five years old. He graduated from the College of New York, his native city, in 1865; took his degree of M. D. at the New York College of Physicians and Surgeons and that of Ph. D. at the

University of Göttingen, in Germany. He also holds the degree of LL. D. from Columbia (1893) and from Princeton (1896). In 1872 he occupied the chair of chemistry in Williams College, and three years later entered Johns Hopkins University in the same capacity.

A Model of a Manila Hospital to be Exhibited at Washington, D. C.—Surgeon-General Sternberg has been advised of the shipment from Manila of an admirable model of Hospital No. 3. It will be placed in the Army Medical Museum, at Washington, D. C. The model is built on the scale of 1 to 250, upon a single square of narra wood, and shows all elevations, drainage, and sanitation. The model includes, besides Hospital No. 3, the hospital corps company of instruction and the hospital corps camp of casuals, which are adjacent and under the same command. The details are made from the original material of the buildings and walls which they represent. Every ward-room, office, tent, hydrant, tree, fence or ditch is reproduced in a miniature size. The gradation of the land surrounding and levels of drains are exact in proportion. It took two months to construct the model.

The Rockefeller Institute for Medical Research.—The generosity of Mr. John D. Rockefeller has established an institute, to be known as the Rockefeller Institute for Medical Research. The purpose of the foundation, as the name implies, is to furnish facilities for original investigation, particularly in such problems in medicine and hygiene as have a practical bearing upon the prevention and treatment of disease. The sum of \$200,000 has been placed at the disposal of the board to begin the work, not as an endowment, but to be used in a series of years for current expenses. The home of the institute will be in New York, although, as will be evident from the make-up of the board of directors, medical men from neighboring cities will share in its management. The board, as at present constituted, is as follows: President, William H. Welch, M. D., Baltimore; vice-president, T. Mitchell Prudden, M. D., New York; secretary, L. Emmett Holt, M. D., New York; treasurer, C. A. Herter, M. D., New York; members, Theobald Smith, M. D., Boston; Simon Flexner, M. D., Philadelphia; H. M. Biggs, M. D., New York.

It is not intended to build at once, but with the funds placed at the disposal of the board, research work will be begun under its direction in several different places. The immediate aims of the board are twofold. First, to shape the lines of the work along which the institute may wisely develop, both in contributions to knowledge and in the application of existing knowledge to humane ends. It is felt that when this is done, such local habitation as the future of the institute shall require can be more wisely planned. The potential value of an institution of this kind, and under such auspices, to medical science and to the interests of humanity can hardly be over-estimated.

St. Louis Medical Society of Missouri.—At the last regular meeting, on Saturday, June 8th, Dr. W. G. Moore read a paper entitled Comparative Treatments of Typhoid Fever.

Medical Society of City Hospital Alumni, St. Louis.—At the last regular meeting, on Thursday, June 6th, Dr. Willard Bartlett read a paper entitled Retained Testicle, with the Surgical Features and Microscopic Find-

ings in Three Cases, and Dr. J. G. Moore reported a case of appendicitis.

The Monroe County (N. Y.) Medical Society recently elected the following officers: President, Dr. Lewis W. Ross; vice-president, Dr. Charles W. Barber; secretary, Dr. William W. Brown, and treasurer, Dr. Clarence A. Greenleaf.

The Massachusetts Medico-legal Society.—At the annual meeting, which was held on Tuesday, June 11th, the following papers were read: The Medico-legal Examination of Blood Stains, by Professor Edward S. Wood, of Boston; The Establishment of Diplomas in Legal Medicine, by Dr. Wyatt Johnson, of Montreal; and The Erickson Murder, by Dr. F. H. Baker, of Worcester.

The Medical Association of the Greater City of New York.—At the last stated meeting, on Monday, June 10th, the order of exercises was as follows: Presentation of specimens, by Dr. A. A. Berg; The Growth of New Bone from the Periosteum, by Dr. J. H. Branth; Retinal Changes Following Cerebral Concussion, by Dr. L. A. W. Alleman; and A Case of Cerebral Concussion and Hystero-epilepsy, by Dr. W. B. Noyes.

The American Dermatological Association.—At its annual meeting, held in Chicago from May 29th to June 1st, the following officers were elected: President, Dr. George T. Jackson, of New York; vice-president, Dr. Joseph Leisler, of Chicago; secretary and treasurer, Dr. F. H. Montgomery, of Chicago; member at large of the council, Dr. H. G. Klotz, of New York. The next meeting will be held in Boston, from September 18 to 20, 1902.

The New York Academy of Medicine.—At the last stated meeting, on Thursday, June 6th, the order for the evening was as follows: Presentation of the portrait of Dr. William H. Thomson, by Dr. W. H. Polk; The Freezing-point of Urine, its Determination and the Inferences which may be Drawn from it, by Dr. J. H. Huddleston; and the Early Recognition and Management of Arterial Degeneration, by Dr. Louis F. Bishop.

The Women's Medical Association of New York.—At the annual meeting of the Women's Medical Association of New York, held at the Academy of Medicine, on May 15th, the following officers were elected for the ensuing year: President, Dr. Mary Putnam Jacobi; vice-presidents, Dr. Josephine Walter and Dr. Frances Merriam Myers; recording secretary, Dr. Marie L. Cleard; corresponding secretary, Dr. Mary D. Rushmore; treasurer, Dr. Caroline H. Le Fevre.

The Southern Illinois Medical Association at its annual meeting, which terminated on May 17th, elected officers as follows: President, Dr. O. A. Dean, of Campbell Hill; first vice-president, Dr. J. A. Helm, of Metropolis; second vice-president, Dr. M. D. Empson, of Hartford; secretary, Dr. O. B. Ormsby, of Murphysboro; assistant secretary, Dr. C. E. Risling, of Murphysboro; and treasurer, Dr. A. T. Telford, of Menard. The next meeting will take place at Carbondale in November.

A Department of Original Research at Bellevue Hospital Medical College.—An announcement of great importance to New York University was made on June

6th by Chancellor MacCracken at the annual commencement ceremonies concerning the Bellevue Hospital Medical College. A department of original research has been organized in the name of the university in the Carnegie Laboratory, and a quarterly magazine has been founded to publish to the world of science the results of the research.

The Association of American Medical Colleges held its business meeting at St. Paul, Minn., on June 3d. The election of officers resulted as follows: President, Dr. Victor C. Vaughan, University of Michigan; first vice-president, Dr. William M. Rodman, Philadelphia; second vice-president, Dr. H. Bert Ellis, Los Angeles; secretary, Dr. Bayard Holmes, Chicago; judicial council, Dr. Thomas Hawkins, Denver, Dr. E. C. Dudley, Chicago, and Dr. W. J. Means, Columbus, Ohio.

The association extended an invitation to the Southern Association of Medical Colleges to unite with the larger organization, and the invitation was accepted. The membership of the association is sixty-five colleges. The accession of the Southern association raises it to seventy-seven.

The Kansas College of Medicine and the University Medical College of Kansas City, which were under suspension for infractions of the rules, were reinstated. Charges preferred against the Hospital College of Medicine, of Louisville, were not sustained.

At the general meeting of the association, on June 3d, Dr. Parks Ritchie, of St. Paul, made an address of welcome.

Dr. Albert R. Baker, of the College of Physicians and Surgeons, of Cleveland, Ohio, compared medical facilities of to-day with those of ten years ago and discussed the requirements of the medical student.

Dr. V. C. Vaughan, of the University of Michigan, read a paper on What Preliminary Education Best Fits a Man for the Study of Medicine? Papers were also read on The Teaching of Anatomy in Medical Schools, by Dr. C. A. Hamann, of Cleveland; The Colleges that do not Give Medical Degrees, by Dean R. H. Whitehead, of the University of North Carolina; The Importance of Keeping Accurate Records of Students' Work and Issuing Specific Records, by Dr. John M. Dodson, of Chicago; Education in Hospital and Laboratory, by Dr. Ludwig Hektoen, of Chicago. An exhibition of pedagogic apparatus and methods closed the afternoon session. The delegates were guests at the State University in the forenoon.

The Harsen Prizes at the College of Physicians and Surgeons.—Trustees of the College of Physicians and Surgeons have established three Harsen prizes for proficiency at the final examinations in practical anatomy, clinical medicine, clinical surgery, and several other subjects. The prizes are \$500, \$300, and \$200, respectively, for the three highest men. It has been the custom to award a diploma of "examination honors" to each of the ten men of the graduating class who pass the best examinations in trying for their doctor's degree. The ten men thus honored are entitled to take part in special competitive examinations, and the three most meritorious competitors receive the first, second, and third prizes, respectively. The winners this year were: First prize Charles Hendee Smith, of Hartland, Wis., graduate of Cornell; second prize, Philip Van Ingen, of New York, graduate of Yale; third prize, William Darrach, of New York, graduate of Yale. The seven other men, who

hold "examination honor" certificates, are James Robert Judd, of Honolulu, Hawaii, a graduate of Yale; Leo Burger, of New York, graduate of the City College; Alfred Carlyle Prentice, of New York, graduate of Alfred University; Robert Willis Shearman, of New York, graduate of Columbia; John Howard Blue, of Montgomery, Ala., graduate of the University of Alabama; Joseph Dayton Condit, of Terre Haute, Ind., graduate of Wabash College, and James Percy McKelvy, of Braddock, Pa. This year's committee of award consists of Dr. James W. McLane, dean of the college; Dr. L. Bolton Bangs, '72, president of the Alumni Association, and a third resident alumnus.

Births, Marriages, and Deaths.

Born.

CUMMING.—At South Atlantic Quarantine, Blackbeard Island, Georgia, on Sunday, June 2d, to Dr. and Mrs. Hugh S. Cumming, a daughter.

Married.

CROSCUP—GOODWIN.—In Brooklyn, on Wednesday, June 5th, Dr. Homer C. Croscup and Miss Bertie Goodwin.

DUNN—MCLWAIN.—In Baltimore, on Tuesday, June 4th, Dr. William Wilcox Dunn, of Richmond, Virginia, and Miss Anne Read McIlwaine.

GROS—PATTON.—In Curwensville, Pennsylvania, on Friday, June 7th, Dr. Edmund L. Gros, of Paris, France, and Miss Honora P. Patton.

HUMMER—GUEST.—In Washington, on Wednesday, June 5th, Dr. Harry Reid Hummer and Miss Norena Guest.

JACKSON—SMALLEY.—In Burlington, Vermont, on Tuesday, June 4th, Dr. J. Holmes Jackson and Miss Caroline D. Smalley.

JOHNSON—FOLSOM.—In Star Prairie, Wisconsin, on Friday, May 27th, Dr. Joseph Johnson and Mrs. C. Folsom.

SCOTT—GARDNER.—In Waterloo, Iowa, on Wednesday, June 5th, Dr. C. H. Scott, of Breckenridge, Colorado, and Mrs. Mary Gardner.

SMITH—BROOKS.—In New York, on Wednesday, June 5th, Dr. Robert Newhall Smith and Miss Susan Pritchard Brooks.

SOThoron—TAYLOR.—In King George, Maryland, on Tuesday, June 4th, Dr. Levin I. Sothoron, of Washington, and Miss Marguerite Taylor.

ZOBEL—GETZ.—In San Francisco, on Saturday, June 1st, Dr. Alfred Zobel and Miss Maybell Getz.

Died.

BLOCH.—In Denver, on Saturday, June 5th, Dr. A. J. Bloch, in the thirty-fourth year of his age.

BOND.—In London, England, on Thursday, June 6th, Dr. Thomas Bond, in the fifty-seventh year of his age.

DALY.—In Pittsburgh, on Sunday, June 9th, Dr. William Hudson Daly, United States Army, in the fifty-ninth year of his age.

GOTTSLEBEN.—In Mayville, Wisconsin, on Thursday, May 23d, Dr. R. A. Gottsleben, in the fiftieth year of his age.

HEALY.—In Plattsburgh, N. Y., on Saturday, June 5th, Dr. Maurice L. Healy, of New York, in the thirty-seventh year of his age.

MERENESS.—In Milwaukee, on Wednesday, May 29th, Dr. Dwight Mereness, in the forty-second year of his age.

OSBORNE.—In Salem, Massachusetts, on Saturday, May 25th, Dr. George S. Osborne, in the sixty-third year of his age.

St. JOHN.—In Periale, Luzon, Philippine Islands, on Wednesday, May 22d, Dr. Charles St. John.

SALE.—In Memphis, on Sunday, June 9th, Dr. E. Paul Sale.

SPRAGUE.—In Jersey City, on Wednesday, June 5th, Dr. Seth B. Sprague, in the sixty-first year of his age.

TERRIBERRY.—In Paterson, N. J., on Sunday, June 9th, Dr. Calvin Terriberry, in the fiftieth year of his age.

TESSON.—In Vancouver, Washington, on Saturday, June 5th, Dr. Lewis S. Tesson, Medical Director of the Department of the Columbia, in the fifty-ninth year of his age.

THIRKELL.—In Sodus, N. Y., on Wednesday, May 29th, Dr. William G. Thirkell, in the sixty-fourth year of his age.

WOODS.—In Boston, on Saturday, June 1st, Dr. William Woods, in the sixty-first year of his age.

Pith of Current Literature.

Medical News, June 1, 1901.

Some Factors Relating to the Ætiology of Prostatic Enlargement. By Dr. J. Bentley Squier.—The author points out that it is an antiquated idea to believe that prostatic hypertrophy is only a senile condition, and he shows that if the sexual history of *prostatiques* is carefully gone into, one will find that a surprising majority have abused their sexual apparatus to a greater or less extent and have kept up a constant hyperæmia of their prostate for years.

Gastric Ulcer and Muco-membranous Colitis at the Paris Congress. By Dr. James J. Walsh.

Streptococcus Bronchitis in Influenza. By Dr. F. Forchheimer.

Fourth-of-July Tetanus. By Dr. H. Gideon Wells.—The author refers to the fact that tetanus is endemic in Chicago, the specific organism being present in the dirt of the streets. An epidemic always occurs on the "Fourth," because then the bacilli are carried deeply into wounds in front of wads from blank cartridges, and are there under conditions favorable for multiplication.

The Use of Methylene-blue Injections in Pleurisy, with Effusion. By Dr. Charles H. Lewis.

The Appearance of the Soft Palate a Pathognomonic Symptom of Epidemic Influenza. By Dr. Louis Koliński.

June 8, 1901.

The President's Address. By Dr. Charles A. L. Reed.—(See *New York Medical Journal*, June 8th.)

Internal Medicine in the Nineteenth Century. By Dr. N. S. Davis, Jr.—(See *New York Medical Journal*, June 8th.)

The Progress and Tendency of Hygiene and Sanitary Science in the Nineteenth Century. By Dr. George M. Kober.—(See *New York Medical Journal*, June 8th.)

Journal of the American Medical Association, June 1, 1901.

Movable Kidney—Its Cause and Treatment. By Dr. L. M. Harris.—The essential cause of movable kidney lies in a particular body form, the chief characteristics of which are a marked contraction of the lower end of the middle zone of the body, with a diminution in the capacity of this portion of the body cavity. The constricted outlet of the zone comes above the centre of the organ, and all acts which tend to adduct the lower ribs press the upper pole of the kidney and crowd it still further downward. These influences gradually produce a movable kidney. A distinctly movable kidney is never the immediate result of a single injury or of external trauma.

The Appendix Vermiformis and Cæcum—A Comparative Study. By Dr. B. Merrill Ricketts.

Zoology in the Medical School Curriculum. By Charles Wardell Stiles, Ph. D.—The author proposes that the subject of animal parasitism be treated in a special course, by a special man, preferably by a zoologist, or else by a physician with a special zoologic or helminthologic training.

Antipneumococcic Serum Treatment of Pneumonia, with Report of Cases. By Dr. G. E. Tyler.

How to Treat Muscular and Joint Sprains of Railway Employees. By Dr. Haldor Sneve.—Immobilization of muscles is not rest, and plaster casts should not be used unless it is impossible to maintain a proper position of the joint. Hydrotherapy is of great value. The counterirritation of static electricity in conjunction with massage is the best treatment for a strain. The ambulatory treatment of sprains in conjunction with massage is today the best.

Diagnosis and Symptomatology in the Appendicitis of Children. By Dr. Thomas H. Manley.

Is it Possible, by Proper Dietetics and Hygiene, to Exterminate Tuberculosis? By Dr. J. E. Kinney.

Variola and Varicella. By Dr. M. A. Austin.

Photographing the Eye-ground. By Dr. Shirks Jackson.

June 8, 1901.

The President's Address, Delivered at the Fifty-second Annual Meeting of the American Medical Association, Held at St. Paul, Minn., June 4, 5, 6, and 7, 1901. By Dr. Charles A. L. Reed.—(See *New York Medical Journal*, June 8th.)

American Medicine, June 1, 1901.

A Case of Antrum Infection and Sigmoid Sinus Thrombosis without Present Middle-ear Disease, Presenting the Symptoms of Facial Neuralgia and None of the Ordinary Symptoms of Disease in the Petrosa: Retropharyngeal Gravity—Abscess, General Sinus Thrombosis without much Impairment of Cerebration. Death after Three Months, Partial Autopsy, Presentation of Specimens. By Dr. Bayard Holmes.

Typhoid Fever and Pharyngeal Diphtheria. By Dr. Morris Manges.

Practical Thoughts on Pulmonary Tuberculosis. By Dr. Howard S. Anders.—The author mentions the use of aromatic oils, the oil of sandalwood, and the oil of erigeron. The first in ten-drop doses every three or four hours, or as needed, affords much relief for the cough in the earlier stages of the disease. Erigeron is of decided benefit in the hæmoptysis of tuberculosis, administered in five-minim capsules every two, three, or four hours.

The Recognition of Tabes Dorsalis. By Dr. Theodore Diller.—The following are the cardinal symptoms of tabes in the order of their importance: (1) Failure of knee-jerks; (2) Romberg symptoms; (3) Argyll Robertson pupil; (4) lightning pains; (5) loss of functions of the bladder or sexual organs.

Simplicity in Therapeutics. By Dr. Edwin Pyle.

The Radical Cure of Internal and External Piles by Excision. By Dr. John A. Hawkins.

Rigidity of the Spine [Spondylose Rhizomélique]. By Dr. Max H. Boehroch.

Two Successful Cases of Secondary Suture, One of the Posterior Interosseous Nerve and One of the Median and Ulnar Nerves. By Dr. W. W. Keen.

Pancreatitis. By A. W. Mayo Robson, F. R. C. S. (Leeds).

The Examination of the Blood in Relation to Surgery of Scientific, but often of no Practical Value, and may Misguide the Surgeon. By Dr. John B. Deaver.

Complicated Fractures, their Diagnosis and Treatment. By Dr. Thomas H. Manley.—The author makes a plea for practitioners treating more fractures at home. If you feel that you are incompetent, take a post-graduate course in this important branch of surgery.

Pityriasis Versicolor, with Special Reference to Allen's Iodine Test. By Dr. Jacob Sobel.

The Biceps Tendon Jerk in Locomotor Ataxia. By Dr. Moses Behrend.

June 8, 1901.

What I have Learned from One Hundred and Sixty-one Operations for the Relief of Senile Hypertrophy of the Prostate Gland. By Dr. Orville Horwitz.—The author speaks very strongly in favor of the operation of suprapubic cystotomy, and he believes that the high mortality sustained by some surgeons must be due to the fact that the patients were not properly prepared for the operation, that the technique was faulty, or that patients were selected whose physical condition was such that any surgical procedure would have been one of great danger.

Progress of Medicine in the United States during the Nineteenth Century. By Dr. Charles W. Dulles.

Membranous Enteritis Erroneously Treated for Phthisis; Presentation of Patient. By Dr. J. Preston Miller.

The Knee-jerks in Chorea. By Dr. Augustus A. Eshner.

Heredity as a Factor in Mental Deficiency. By Dr. T. Alexander MacNichol.

Medical Record, June 1, 1901.

The Diagnosis and Surgical Treatment of Prolapsed Kidney, with Demonstration of a Simple Method of Examination for its Detection. By Dr. Augustin H. Goelet.

The Climate of Long Island. By Dr. Le Grand N. Denslow.—The author recommends this climate in those cases of heart, lung, kidney, and rheumatic troubles in which rapid oxidation is desirable in a sunshiny, dry, slightly stimulating climate at a low level.

Superheated Air in the Therapeutics of Chronic Catarrhal Otitis Media. By Dr. George W. Hopkins.

Three Cæsarean Sections—Recovery. By Dr. J. F. Baldwin.

Ether as an Anæsthetic. By Dr. Edward Judson Wynkoop.—The author believes that the time is ripe for the profession of this city to support a man who makes it his business to give anæsthetics and to administer them properly. He advocates the use of ether as being the safest of anæsthetics, but he believes that this fact should not lessen our caution, and he asks for a more detailed study of this important subject in our schools and hospitals.

A Few Observations from the Lorenz Orthopædic Clinic. By Dr. Leonard W. Ely.

A Case of Membranous Angina, Due to Streptococci, Followed by Paralysis of the Soft Palate. By Dr. Moses Keschner.

June 8, 1901.

The President's Address, Delivered at the Fifty-second Annual Meeting of the American Medical Association, Held at St. Paul, Minn., June 4, 5, 6, and 7, 1901. By Dr. Charles A. L. Reed.—(See *New York Medical Journal*, June 8th.)

Boston Medical and Surgical Journal, May 30, 1901.

The Diagnosis and Surgical Treatment of Renal Tuberculosis. By Dr. F. Tilden Brown.—Too great pains cannot be taken to determine the location and extent of the disease before determining the treatment. In ward hospital cases the immediate operation appears to be the only alternative. For those who can afford climatic changes and rest, a careful preliminary examination of the existing condition of the urinary tracts should precede their travels, and the same examination, when at all indicated, should be repeated in order to keep posted regarding such an advance of the disease as to call for operation.

Asthma. By Dr. F. P. Emerson.

A Case of Trichinosis. By Dr. George G. Sears.

June 6, 1901.

The Value of Clinical Microscopy, Bacteriology, and Chemistry in Surgical Practice. By Dr. John A. Wyeth.—(See *New York Medical Journal*, June 8th.)

The Surgical Treatment of Gastric Ulcer, with Report of Cases. By Dr. F. B. Lund.—The author makes the following points in conclusion: 1. In perforation, immediate operation is absolutely indicated. 2. In cases in which the symptoms fail to yield after medical treat-

ment for a reasonable period, operation, consisting either of excision of the ulcer or gastro-enterostomy, should be performed, and this before the patient has become so exhausted as to render surgical intervention dangerous. 3. In hæmorrhage, where slight, frequently repeated bleeding promises to produce grave anæmia or exhaustion, similar early operation should be done. 4. Where a patient has suffered more than one copious hæmorrhage, operation should be performed, and the extent and nature of the procedure should be decided upon according to the power of the patient to withstand operative manipulations and the conditions found during the progress of the operation.

Idiopathic Abscess of the Kidney. By Dr. A. T. Cabot.

The Effects of Training; Second Paper. By Dr. Eugene A. Darling.—The author gives an interesting series of observations upon the members of the Harvard rowing and football squad during and after training. He found that no ill effects which could reasonably be attributed to training were to be discovered nine months after stopping the training.

Lancet, May 25, 1901.

The Operative Treatment of Abscess when Situated in the Brain. By C. A. Ballance, F. R. C. S.—After making some general remarks on the subject of brain abscess, illustrated by numerous poetical citations, the author describes the various steps of its operative treatment as follows:

1. *Sterilization of the skin.* Shave the scalp, scrub with ethereal soap and water, wash with sterilized water, rub with turpentine on a swab, and then with ether, concluding with strong carbolic or perchloride lotion.

2. *Anæsthesia.* The anæsthetic should be chloroform, warily given, for in cases of cerebellar abscess respiration is apt to cease.

3. *Incision of the scalp.* A flap is to be preferred to a crucial incision; it should be large, and cut with its base downward.

4. *Opening in the bone.* The opening should be free, and the trephine used should be five eighths of an inch in diameter. In temporosphenoidal abscess the site of application should be about seven eighths of an inch above the supramental spine. In cerebellar abscess the anterior edge of the trephine should touch the posterior border of the mastoid process. When the disc of bone has been removed, more bone should be cut away with small saws, forceps, or Cryer's drill.

5. *Incision of the dura mater.* Here, again, a flap is preferable to a crucial incision. Care must be taken not to wound the vessels of the cortex.

6. *Discovery and incision of the abscess.* The best instrument to use is a sharp-pointed, long, and narrow knife. The use of a trocar and cannula or a pus-seeker is unnecessary and contrary to sound surgical principles.

7. *The further treatment of the abscess.* If the cavity is not entirely enclosed by brain substance, it may be gently irrigated with a weak antiseptic solution, a drainage tube being inserted for the escape of the fluid. Normal saline solution is the best to use. Packing with gauze should not be used unless the cavity is very large.

8. *Closure of the wound and dressing.* An aperture is made in the base of the flap the size of the opening in the brain, and the edge of the flap is placed in position and sutured with fine silk-worm gut. Sterilized cyanide gauze is used as a dressing.

9. *After-treatment:* (a) The primæ viæ should be

kept open by some preparation of mercury; (b) barley water and beef tea are often borne by the stomach when milk is rejected; (c) alcohol should be given in some form; (d) hernia cerebri is an evidence of sepsis.

10. *Recurrence of symptoms.* It is by no means uncommon to have a return of symptoms a few days after the evacuation of the abscess, due to the refilling of the old abscess, or to the formation of a new one in the same lobe.

The Pathology and Diseases of the Thyreoid Gland. By W. Edmunds, F. R. C. S.—In the third of the Erasmus Wilson lectures upon this subject, the author takes up the question of treatment. With respect to cases of sporadic goitre without symptoms—that is to say, cases in which the presence of the goitre is the only trouble—it seems now to be clearly established that the administration of thyreoid gland is the best treatment. The effects of this treatment are so good that it must be regarded as a specific remedy. Formerly goitres were occasionally treated by excision, but the constitutional results following this operation were so serious that complete excision is now abandoned. Among these results were weakness of body and mind, deficient peripheral circulation, œdema, bulkiness of the face, dryness of the skin, falling out of the hair, and arrest of bodily and mental development. It is best to include under the term "Graves's disease" all cases of goitre with symptoms not to be explained by pressure. The treatment of Graves's disease has been carried out on various lines. The most obvious treatment is rest; change of air and quietude are also obviously indicated. Of drugs, belladonna stands in the best repute; bromide of potassium, digitalis, quinine and iron are also given. Thyreoid extract gives different results in different cases; in some it benefits and in others it makes matters much worse. Pregnancy, when it occurs, is often of marked benefit. Graves's disease has been treated by operative methods. These are three—namely (1), operations on the cervical sympathetic, which are rarely of any service; (2) ligation of three of the four arteries to the thyreoid gland, an operation which has met with a measure of success, but there may be difficulty in reaching the arteries behind the enlarged thyreoid gland; and (3), excision. The danger in these latter cases seems to be of sudden death, yet this often occurs in cases that are not operated upon. The author suggests that such cases teach us, not that operations should not be performed, but that they should be performed earlier. The author has seen two cases of Graves's disease treated by excision; both patients recovered entirely.

The Surgical Treatment of Chronic Ulcer of the Stomach. By A. W. Mayo Robson, F. R. C. S.—The surgical treatment of intractable or relapsing gastric ulcer is in the greater number of cases the only satisfactory method of dealing with them, and operation should be resorted to at a much earlier period than has hitherto been the custom, and always before the patient has been reduced by pain or starvation. The author describes the various operations performed for chronic ulcer of the stomach, citing numerous illustrative cases. Preliminary cleansing of the stomach is in most cases quite unnecessary and inadvisable.

Exploratory gastrotomy is an operation occasionally called for: (1) In order to verify the diagnosis of ulcer, where there is much thickening of the stomach walls; (2) when the characteristic signs, such as puckering, etc., are absent from the external surface of the stomach; (3) in certain cases of gastrorrhagia, where the bleeding

vessel must be found and tied; and (4), it forms part of any operation for the excision of ulcer of the stomach. Such excision is, as a rule, unnecessary, but not always to be avoided. Pylorotomy is an operation which may be mentioned under the head of excision of ulcer.

Gastro-enterostomy, in the absence of special complications, is the operation to be relied on in the treatment of ulcer of the stomach. It secures physiological rest by means of drainage, relieves pyloric spasm, and diminishes gastric fermentation and dilatation. The author describes his own method of anastomosis—suture over a decalcified bone bobbin—and claims the following advantages therefor: 1. It secures the opening being of the exact size intended. 2. It secures an immediately patent channel between the two anastomosed viscera. 3. The bobbin protects the new line of union from pressure for from twenty-four to forty-eight hours. 4. It facilitates the application of the sutures. 5. No foreign material is left in the alimentary canal, as the bobbin rapidly dissolves in the gastric juices. 6. The method has been proved by ample experience to be rapid, efficient, easy, and safe.

Pyloroplasty has certain very definite limitations, but, where feasible, is a method of great utility which can be performed rapidly and with little exposure of viscera. It is only indicated in cases of spasmodic stenosis and in slight annular stenosis, being too dangerous in all other cases.

Pylorodiosis, or stretching of the pyloric sphincter, is a method of little practical value in the treatment of ulcer. The cases almost always relapse.

Analyses of Stools and Urine from Epileptic Patients under Treatment with "Brominol" Compared with Similar Specimens from Patients under Potassium Bromide. By W. H. Martindale, Ph. D.

Two Cases of Carcinoma Treated with Cacodylate of Sodium. By E. M. Payne, M. B.

Acute Colitis in Children. By Dr. E. Cautley.—The author reports a small but very definite outbreak of acute colitis, observed by him in London. Six out of thirty children were affected, and of these four died. At the post-mortem the whole of the large intestine was found to be inflamed and thickened, the inflammation also affecting the lower end of the ileum. Very little ulceration was to be noted. In each case the onset was sudden, with vomiting, diarrhoea, and pyrexia. The treatment must be directed to maintaining the strength of the patient and stopping the diarrhoea and vomiting. Warmth and rest in bed are essential. Irrigation is difficult to carry out, and seems to be of very little service.

June 1, 1901.

Acroparæsthesia, Erythromelalgia, Sclerodactylia, and other Angeioneurotic Disturbances. By Dr. T. D. Savill.—The author reports seven cases which illustrate fairly well some of the many different symptoms of angeioneurotic disorder. Acroparæsthesia, erythromelalgia, and some of the other many and varied vasomotor symptoms have certain features in common: 1. They are much more frequently met with in the female sex, something like ninety per cent. of these cases occur in women. 2. Vasomotor conditions appear to be due to some inherent and very often inherited tendency in the patient, for they recur again and again in one form or another during the life of a patient. Two epochs of life are specially prone to their development—namely, puberty and the climacteric. 3. The onset of the symptoms, whatever they may be, is always more or less sud-

den. 4. They are in all cases paroxysmal, *i. e.*, they occur in the form of attacks. 5. In the great majority of the patients flushes or flush-storms occur from time to time during the patient's life; should these be absent, there are generally other evidences of vasomotor instability. 6. Many cases, particularly of the vasodilator kind, are amenable to treatment by the bromides, which relieve them, at any rate, for a time. In conclusion, the author gives the following clinical classification of vasomotor disorders of the extremities:

A. Vaso Dilatation—(a) Early Stage (Chronic).—Attacks of redness (congestion) and tingling, burning, etc. (*congestive acroparæsthesia*). *(b) Late Stage (Chronic).* The symptoms are attended by swelling, which gradually becomes permanent (*erythromelalgia*). *(c)* If the process takes an *acute* course, the symptoms go on to gangrene, usually moist gangrene (*Raynaud's disease*, congestive or asphyxial type).

B. Vasoconstriction—(a) Early Stage (Chronic).—Attacks of pallor and bloodlessness (*ischæmia*), attended by numbness, tingling, "pins and needles," "dead fingers," etc. (*ischæmic acroparæsthesia*). *(b) Late Stage (Chronic).* The symptoms may be attended with thickening (sclerosis) of the skin and subcutaneous tissue (*sclerodactylia*). *(c)* If the process takes an *acute* course, dry gangrene probably results (*Reynaud's disease*, syncope type).

Arterial Hypertonus and Arteriosclerosis: Their Relations and Significance. By Dr. W. Russell.—The author holds that atheroma and arteriosclerosis are distinct affections. Atheroma is a primary affection of the tunica intima of the arteries, degeneration and destruction of the media being secondary. The author has made histological examinations of the blood-vessels in sixteen cases of arteriosclerosis, all of which were seen by him during life. His results may be stated as follows:

1. Atheroma and arteriosclerosis are two totally distinct clinical and pathological entities. 2. Atheroma is a localized and patchy affection of the arteries characterized by degenerative changes which have long been recognized. 3. Arteriosclerosis is a generalized affection of the arteries and is characterized by *(a)* thickening of the tunica media, this thickening being primarily a true hypertrophy, although it may ultimately show some degeneration; *(b)* thickening of the tunica intima from fibrous hyperplasia of the subendothelial connective tissue without atheromatous degeneration; and *(c)* in some instances fibrous thickening of the tunica adventitia. 4. The atrophic changes in the kidneys are in proportion to the sclerotic changes in the vessels. 5. The lumen of the arteries in the kidneys and of the radial arteries is markedly diminished. 6. The changes in the nutrient arteries of the brain and spinal cord correspond with those of the arteries inside the kidneys. 7. Arteriosclerosis may be associated with more or less atheroma in the same subject.

The author emphasizes the importance of the recognition of the state of contraction of the vessel wall. To the exaggerated tonicity so frequent in arteriosclerosis he gives the name of "hypertonus." Hypertonus carries with it, besides the alteration in blood pressure, a diminution in the blood-containing capacity of the vessels from a diminution in their lumen. It can be recognized or suspected by the educated finger. It occurs in normal arteries and in sclerosed arteries, in the young, middle-aged, and old. And most of the symptoms of arteriosclerosis are mainly attributable to the hyper-

tonus lowering the blood supply to organs which are already badly supplied by the sclerosed arteries. In the majority of cases it is produced by the introduction of poisons into the body or by self-intoxication. Recurring or continued hypertonus leads to hypertrophy of the muscular media of the arteries. The thickened intima is to be explained by the circulation in the blood of deleterious substances of various kinds. We thus get the completed picture of arteriosclerosis, but the evolution of the changes occupies a varying time in different persons.

The Bacteriology of Sporadic Cerebrospinal Meningitis. By W. Hunter, M. B., and A. W. Nuthall, F. R. C. S.—The authors have examined bacteriologically the cerebrospinal fluid obtained by lumbar puncture from ten cases of meningitis, nine in children and one in a young adult. Their conclusions are as follows: 1. In all the cases of meningitis examined a diplococcus was isolated from the cerebrospinal fluid. In nine cases the fluid was obtained by lumbar puncture during life. 2. This diplococcus had the same morphological and biological characteristics as Weichselbaum's *Diplococcus intracellularis meningitidis*. 3. In some cases the diplococcus was present in pure culture, in others associated with other micro-organisms, e. g., *Bacillus influenzae* and *Bacillus tuberculosis*. 4. The clinical picture and the pathological changes found in these cases were those met with in so-called "posterior basal meningitis." 5. In all probability "posterior basal meningitis" is simply a sporadic manifestation of cerebrospinal meningitis and is produced by the same micro-organism—namely, the *Diplococcus intracellularis meningitidis*.

On the Operative Treatment of Corneal Astigmatism. By Dr. A. Bréuer.

A Further Note on the Technique of the Quantitative Estimation of the Bactericidal Power of the Blood, and (Incidentally) on the Possible Application of such Estimations to the Standardization of Bacterial Vaccines. By Dr. A. E. Wright.—In this article the author makes his third communication upon this subject. He has introduced certain simplifications into his methods, the chief of these being a substitution of a glass spiral in the neck of his capillary culture tube for the cotton-wool plug previously employed. He has also simplified his method of determining the number of bacteria present in the typhoid culture employed, and describes the method in detail. Examples are given of a series of bactericidal determinations made precedent to anti-typhoid inoculation and in the negative phase which supervenes upon inoculation where relatively large doses of dead bacterial cultures are inoculated.

British Medical Journal, May 25, 1901.

Appendicitis and its Surgical Treatment. By Dr. J. C. Renton.—Inflammatory affections of the appendix vermiformis may be divided into three forms: 1. Catarrhal, with no distinct lump or swelling around the appendix. 2. Appendicitis with a swelling which may entirely disappear, either by absorption or by the formation of a local abscess which may require an operation or may burst into one of the viscera, such as the bowel or bladder, or more seriously into the free abdominal cavity. 3. Acute perforating appendicitis, which leads to general peritonitis and the formation of abscess in the general peritoneal cavity. The author briefly reviews the symptoms, prognosis, and indications for operation in these three forms of appendicitis. After a second

catarrhal attack the operation for removal of the appendix, when possible, ought to be done after all acute symptoms have subsided and after the patient has been carefully prepared for it. In appendicitis with swelling always examine the rectum; if bulging is detected, the abscess should be opened at that point. Exploring such appendiceal swellings with ordinary exploring needles is most unwise. Cases of acute perforating appendicitis should be put in the same category as ruptured gastric or typhoid ulcer and be operated upon the moment the symptoms point to acute perforation.

The Symptoms and Modern Methods of Diagnosis of Stone in the Bladder, Kidney, and Ureter. By Dr. P. J. Freyer.—The characteristic symptoms of stone in the bladder are four in number: (1) Increased frequency of micturition; (2) pain in connection with urination; (3) hæmaturia; (4) sudden stoppage of the flow of urine.

After dwelling briefly on these various symptoms and the other conditions which may give rise to them singly, the author goes on to describe the methods of diagnosis of stone in the bladder. The most important of these is by sounding. Before sounding, however, a rectal examination by the finger should be made to ascertain the state of the prostate gland, the existence of organic deposit in the base of the bladder, or of inflammatory thickening of the vesiculæ seminales. There is no more harmless procedure in surgery than sounding, if conducted with care and skill. Never use force, never give pain, and never draw blood if possible. The best sound is Mercier's simple, solid steel sound, with its short, well-curved beak and bulbous end. The best size for general use in adults is No. 6 of the English scale in the shaft, increasing to No. 10 in the bulb; for children No. 2 in the shaft and No. 5 at the bulb. Small stones may often be detected by means of the aspirator and cannulæ employed in Bigelow's operation. Finally it may be necessary to open the bladder either perineally or suprapubically.

In renal calculus the two characteristic symptoms are pain in the loin and hæmaturia. A typical, almost pathognomonic, characteristic of both is that they are brought on or increased by exercise, particularly horse-back riding. The presence of mucus and pus in the urine are also important symptoms. The Röntgen rays are of service in some cases.

The symptoms of stone in the ureter are, as a rule, extremely obscure. The most important means of diagnosing a calculus lying in the lower end of the ureter or projecting from its orifice is Leiter's electric cystoscope. The author cites three or four instances of its successful use.

Notes on Two Hundred and Six Operations for Stone. By W. F. Adams, M. R. C. S.—The author reports 206 cases of operation for stone, as shown in the following table:

Urethral calculi extracted through the meatus.....	4
“ “ with incision of the meatus.....	3
“ “ by external urethrotomy.....	2
Vesical calculi removed by lithotripsy (male 153, female 8).....	161
Vesical calculi, perineal lithotomy (3 median, 33 lateral).....	36
Total cases.....	206

Three cases of lithotripsy and three of lithotomy ended fatally. Total deaths, 6.

The contraindications for lithotripsy are: I.—*In Boys*. 1. When there is marked cystitis, lithotomy drains the bladder and cures both diseases. 2. When there is much difficulty in passing instruments. 3. When the stone is too large or too hard for the necessarily small lithotrite. 4. When there are indications of advanced kidney disease or great debility, the shock of the cutting operation seems less severe, probably because it is briefer. II.—*In Men*. 1. When the instruments cannot be passed. 2. When the stone is too large or cannot be grasped.

A Method of Sterilizing Soft Catheters. By H. T. Herring, M. B.—The author describes an apparatus for the easy and rapid sterilization by steam of soft-rubber catheters and their lubricant. It consists of a series of metal tubes for containing the catheters, which tubes are attached to a metal flask containing water and liquid paraffin. On heating the flask the boiling water ascends into and sterilizes the tube and the catheter is coated with the sterile paraffin. The tubes are then plugged with sterile rubber corks and laid aside for use.

A Case of almost Universal Ankylosis. By Dr. T. K. Monro.—The author reports the case of a man who died at the age of forty-six years, who had been afflicted since his eighteenth year with almost universal arthritic ankylosis. The disease in each joint began with pain, followed by swelling and fixation. The case appeared to correspond to the subacute type of the very rare disease known as "universal bony ankylosis or arthritis ossificans." Such cases constitute what are popularly known as ossified men.

Strangulation of Meckel's Diverticulum. By Dr. K. Campbell.—The author reports a case of intestinal obstruction in a man, aged over seventy years, due to strangulation of Meckel's diverticulum. No operation could be performed owing to the collapsed condition of the patient, and the lesion was only discovered at autopsy. The chief danger of these persistent diverticula is usually considered to be the risk of strangulation of the other abdominal contents, on account of the presence of a fibrous band within the abdominal cavity. The patient had lived a long and active life without any inconvenience arising from this irresponsible appendage.

Case of Cancer of the Larynx with a Long Course. By E. Donaldson, B. A., T. C. D.—The author reports a case of cancer of the larynx occurring in a woman, which was chiefly remarkable for its long duration, *viz.*, nine years and one month. For a long time a benign growth was diagnosed, and the disease was allowed to run its course unmodified by the more radical methods of treatment. A warty laryngeal growth in an elderly person may present symptoms of a benign tumor for about eight years, and in the end turn out to be malignant.

Furunculosis of the External Auditory Canal Simulating Mastoid Periosteitis. By J. G. Connal, M. B.—The author calls attention to a type of auditory furunculosis with oedematous swelling over the mastoid process, simulating mastoid disease. He reports two such cases, in both of which the furuncles were opened in the external auditory canal, and the patients made uninterrupted recoveries. The cultures from both cases showed the presence of the *Staphylococcus pyogenes aureus*.

June 1, 1901.

Theories of Inheritance, with Special Reference to the Inheritance of Acquired Conditions in Man. By Dr. J. G. Adami.—(See *New York Medical Journal*, June 8th, page 925.)

The Pathogenesis of Tabes and Allied Conditions in the Cord. By C. Watson, M. B.—The author does not believe that tabes is a primary disease of the nervous system, but that the lesions in and around the vessels are of primary importance, the lesions of the neurones being determined by interference with the local blood supply. Further, there is good ground for the belief that the condition is dependent upon a chronic self-intoxication, the vascular lesions being to some extent general, but tending to be more advanced locally, and that the more advanced local changes determine a failure of nutrition in the adjacent nerve elements. If these views are correct, the condition should be curable in the early stages and the present tendency to separate tabes sharply from other diseases in which there is a well-marked lesion of the cord of an allied character is to be deprecated. In cases of recovery one of two things occurs: (1) The toxins disappear from the tissues or diminish sufficiently to lead to the disappearance of symptoms—in other words, a diminished absorption takes place; or (2), the resisting power of the animals increases, due to a gradually acquired immunity. The author maintains that the syphilitic origin of tabes is a mere *non sequitur*, from the fact that a syphilitic history can be traced in a large number of tabetic subjects. The broadest conclusion which we can deduce from that fact is that syphilis alters the physiological condition in such a way as to favor the attack and operation of the actual cause of tabes and allied conditions. In this respect its influence is similar to that of measles or scarlet fever in leading to the development of tuberculosis. The proper line of investigation is the discovery of the nature and source of the toxic substance at work. The alimentary tract furnishes the chief area of investigation, and in all probability it will be proved to be the original source of the toxæmia.

Case of Malignant Disease of the Lung, with Pseudo-tuberculosis. By Dr. H. B. Shaw.—The author reports the case of a man, aged twenty-seven years, who suffered from malignant disease of the left lung. At the autopsy there was found a sarcoma of the root of the left lung, producing stenosis of the bronchus and vessels, and associated with pneumonia of the lung, probably due to the septic organisms present. The lung condition so closely resembled that met with in tuberculosis, with the exception that the process was more marked at the base than at the apex, as to merit the application of the term pseudo-tuberculosis. The author reviews the literature of the association of tuberculosis and malignant disease of the lung, and finds that the number of cases of progressive tubercle of the lung occurring in association with any form of malignant growth of the lung is very small—that is, if the absolute evidence of the presence of tubercle bacilli in the tissues is relied on. In the case here reported repeated examinations for tubercle bacilli were uniformly negative.

Sequel to a Case of Pulmonary Hypertrophic Osteoarthropathy: Necropsy. By E. F. Buzzard, M. B.—The author reports the autopsy findings in a case of pulmonary hypertrophic osteoarthropathy, which had been under observation for some time. The main features of interest were as follows: A pus-containing cavity was found at the root of the right lung, which was in direct continuity with a passage that passed into the intervertebral space between the third and fourth dorsal vertebrae, where there was a marked curvature of the spine. The dura mater at that point was covered with thick granulations. There were no conclusive evidences of tubercle of the lungs. Dissection of the clubbed fingers showed the interphalangeal joints to be intact, and there

was very little actual enlargement of the terminal phalanx. The bulbous ends of the fingers contained subcutaneous fat in excess. The other organs were normal. The examination of the nervous system, by the best methods now at our disposal, did not reveal the presence of any nervous lesion to support the supposed neurotic factor in the causation of the deformities.

The Pulse Rate in Pulmonary Tuberculosis. By Dr. T. Campbell.—In attaching a significance to the pulse record in cases of pulmonary tuberculosis, allowance must be made for the possibility of over-exertion, excitability under examination, and the presence of mitral stenosis; but, with these reservations, some assistance will be obtained in making a pronouncement regarding the probable duration of life. Cases in which a tuberculous area has been cleared out by excavation, followed by a period of quiescence during which the cardiac pulsations may not exceed eighty-four per minute, are suitable for treatment in a sanatorium, as there is a likelihood that life can be considerably prolonged. But a pulse of 100 or more, accompanying an evening temperature of 101° F., and these two signs of grave import being persistently present in a case in which absolute rest has been enforced for some time, give little hope of treatment proving of any avail. As acceleration of the pulse is found at the onset of the pulmonary affection, so a gradual fall will be found to take place if a case is making progress toward recovery.

The Position in which the Regurgitant Aortic Murmur is most Clearly Audible at the Base of the Heart. By Dr. H. W. Syers.—The author calls attention to the fact that in at least ninety-five per cent. of the cases in which aortic reflex occurs the diastolic murmur is heard much more loudly at the second left interspace, close to the sternum, than in the position usually assigned to it—namely, the second right interspace. And the point at which the murmur is heard loudest of all is almost invariably the middle of the sternum, and it is frequently very loudly audible just above the xiphoid cartilage. Aortic regurgitant disease is the most likely to be overlooked of all valvular lesions, hence the importance of not limiting the examination to any one particular area.

The Development of Filaria Nocturna in Different Species of Mosquitoes. By G. C. Low, M. B.—The results of the author's observations on this subject may be summed up as follows: Some mosquitoes are inefficient hosts, the filaria embryos never migrating from the stomach; some are partially efficient, the embryos reaching the muscles, where they undergo a partial development and then become absorbed; while others are properly efficient, the time taken for complete metamorphosis varying with the temperature and other climatic influences of the place in which the experiments are conducted. Experiments to determine the intermediate host of *Filaria demarquaii* have so far proved entirely negative.

Note on the Value of Experiments in the Question of Food Preservatives. By Dr. A. S. Grünbaum.—The author criticizes the report of Rosenheim and Tunncliffe on this subject, who found that neither boric acid nor borax in any way affected the well-being of children, when added to their food as preservatives. The advisability of permitting or prohibiting the addition of preservatives to food does not depend entirely upon the fact of whether experiment shows them to be harmless or harmful. The fact that the commonly employed antiseptic preservatives are rapidly eliminated by the kid-

neys, either unchanged or only slightly changed, is the most conclusive evidence of their poisonous character. It throws an uncalled-for burden on the normal kidney, and, where the kidney is no longer normal, may be positively dangerous. The use of preservatives tends to dirtiness and fraud.

Presse médicale, May 11, 1901.

Spinal Cocainization.—M. Reclus takes issue with Tuffier as to the harmlessness of intra-arachnoid cocainization for purposes of anaesthesia. He records several cases from the literature of prolonged unconsciousness, of cyanosis, of syncope, and of collapse. He regards the action of cocaine injected in this way as uncertain and not always the same. [Although the article is polemic in its nature, it is worth perusal as showing the gravity and possible dangers of this method of inducing anaesthesia.]

Mucomembranous Enterocolitis.—M. Langenhagen gives an exhaustive review of the subject. The three cardinal points in the treatment are rigorous diet, methodical enteroclyses, and baths properly applied. The diet should be nourishing and may embrace eggs, fried or boiled white fish, lentils, peas, beans, potatoes, and roasted meats. Boiled water should be used for the enemata, at a temperature of from 100° to 105° F., and should be allowed to run into the rectum without too great pressure. From six to ten quarts should be used by means of a rectal tube. The baths should be subsequently taken at Plombières or Châtel-Guyon.

Lyon médical, May 12, 1901.

Hernia as an Accident of Work.—M. Jean Boyer, in a forensic review of this subject, says that under certain circumstances a hernia may result as a sequel to the work in which the patient is engaged, but it should then devolve upon the interested person to prove this fact to the court and to the physician.

Elective Diapedesis of Eosinophilia. By M. C. Bonne.

Centralblatt für innere Medicin, May 18, 1901.

Immunity to Poisons.—Dr. Mario Carrara finds, as a result of his experiments, that the lethal dose of strychnine sulphate is the same in animals whose muscles and connective tissue are refractory to the drug, as guinea-pigs and chickens, as in susceptible animals like the rabbit. He concludes, therefore, that the muscles and muscle juices of the refractory animals do not account for their apparent immunity, which still remains a mystery.

Centralblatt für Chirurgie, May 18, 1901.

Magnesium for Absorbable Intestinal Buttons.—Dr. Erwin Paye says his further experiences have demonstrated the utility of magnesium, which is readily absorbable, not only for intestinal anastomosis, but for the control of parenchymatous hæmorrhage in internal organs, for joint surgery, for nerve sutures, and for the ligation of blood-vessels.

Deutsche Medizinal-Zeitung, May 16, 1901.

Asthma and its Treatment.—Dr. W. Brügelmann says that cases of nervous origin require sedative treatment or even hypnotism for their relief. Asthma of reflex origin demands treatment of the nose or throat, of the female genitals, massage, hydiatics, etc. Iodide of potassium and chloral are good in pharyngeal or nasal

eases, and atropine is exceedingly useful in allaying attacks. In every case an accurate diagnosis of the exact cause of the asthma must be made if a cure is looked for.

Wiener medicinische Blätter, May 16 and 23, 1901.

Diagnosis of Diabetes Mellitus.—Dr. J. Herriek says two symptoms demand particular attention, namely, impotence and psychic disturbances. The digestive tract gives characteristic symptoms, such as a dry mouth, stomatitis, gingivitis, falling out of the teeth. The stomach retains its functional activity under remarkable circumstances. Constipation is common, and vomiting and diarrhoea are bad prognostic signs. Furunculosis, eczema, dermatitis, or gangrene may appear in the skin. Arteriosclerosis and its complications may be present. Lipæmia is not uncommon. The paper closes with methods of testing for urinary sugar.

General Ætiology and Pathogenesis of Diabetes Mellitus. By Dr. Heinrich Stern. (*Continued article.*)

Riforma medica, April 26, 1901.

First Aid in Wounds of the Pancreas. By Dr. Giovanni Ninni.—Literature records but ten cases of wounds of the pancreas, the present case being the eleventh. The rarity of these wounds is due to the situation of the organ, but when they do occur they are grave because they are usually complicated by wounds of other organs. The patient whose case is here reported was a man, aged twenty-seven years, who was shot from the rear by the police in pursuing him—a fugitive from justice. The entrance wound was at the level of the second lumbar vertebra, near the spinal column, the wound of exit in the epigastric region, on the right side between the mammary and parasternal lines, a finger's breadth below the arch of the ribs. The patient was immediately brought to the hospital, where he arrived in a critical condition. His pulse was filiform, and he was scarcely conscious. The abdomen having been opened, the stomach and the liver were found intact, but there were six penetrating wounds in the small intestines and one at the hepatic angle of the colon. These were sutured by Czerny's method, and the toilet of the peritonæum was made. Bleeding was then discovered issuing from the posterior region of the cavity, between the colon and the stomach. The abdominal wound was then enlarged and the stomach and colon were raised. A wound of the pancreas, at the junction of the head and the neck, was then discovered and sutured. The patient recovered.

Vratch, April 14 (April 26, N. S.), 1901.

The New Institute for Massage at the University of Berlin. By Dr. I. V. Zabloudovsky.—This institute was opened in December, 1900. Its purposes are to teach massage in all its phases to students and physicians. Half-yearly courses are given, but there are also shorter courses of four weeks each, including lectures and practical exercises. At first the students practise the various movements on healthy, well-nourished persons who are specially paid for submitting to this massage at the designated hours. Then patients are assigned to the students, and they are required to administer the proper massage treatment as outlined by the lecturer. In this way the technique and the indication for the various forms of massage are taught. The institute also instructs nurses in massage, the course lasting several months, and being chiefly practical.

On the Mechanism of the Action of Pilocarpine on Glands. By Dr. L. B. Popelsky.—Injection of pilocar-

pine into the blood of cats did not produce an increase of the pancreatic secretion. If a solution of hydrochloric acid, 0.4 to 0.5 per cent., is injected into the duodenum of these animals after the pilocarpine has been injected into the blood, the amount of pancreatic juice secreted will be increased. In these experiments the author used cats in which the pancreas was not working before the injection of the pilocarpine, and it was necessary to test many cats every time before one could be found with this pancreatic deficiency. In these, the simple injection of acid into the duodenum did not produce any pancreatic secretion, the latter followed only upon the injection of pilocarpine into the blood, together with the introduction of hydrochloric acid into the duodenum. Injection of pilocarpine alone did not give rise to pancreatic secretion, although it stimulated the salivary and sweat glands almost immediately. The author at first thought that the reason why the pancreas was not equally stimulated was that the pancreatic secretion lacked fluid as a result of the increased elimination through the sweat and the saliva. He therefore injected salt solution into these cats, and found that there was no increase in the pancreatic secretion, and that the assumption had been false. If the cats were fed four or five hours before injecting the pilocarpine, there was an increased secretion of the pancreatic juice, because the gastric juice gradually penetrated into the duodenum and there acted like the artificially introduced hydrochloric acid, stimulating the pancreas to activity. The author concludes that pilocarpine stimulates the pancreas only then when the gland is stimulated from an outside source at the same time. This pilocarpine accomplishes by increasing the susceptibility of the gland cells to stimulants and not by paralyzing the inhibitory nerves of secretion which are found in the nerve bundles of the vagus.

On the Question of the Action of Currents of High Tension upon the Human Body. By Dr. S. A. Broustein.—The author points out how frequently accidents occur with "live" electric wires conducting currents of high tension, such as are used for street lighting, locomotion, etc. These accidents, he says, are especially frequent in the United States, and not quite so common in Russia, on account of the fact that less electricity is used in the latter country at present. He has studied the effects of these currents on the human body, and the cause of death in cases of accident with these wires. The appearances met with after such an accident remind one strongly of shock, or of concussion of the brain. Shock is, however, not identical with the action of electricity in these circumstances. In shock there is no loss of consciousness, the danger increases with the duration of the condition, and the prognosis is bad. On the other hand, in electrical injuries there is almost always loss of consciousness, the danger to life is greatest at the first moment and decreases with the duration of the condition, so that all deaths from electric currents cannot be attributed to shock. Again, the symptoms of brain concussion are distinct from those of electric trauma. (*To be continued.*)

Haffkine's Lymph and other Remedies against the Plague which Give Rise to Active Immunity. By Dr. A. F. Vignr.—A comparative study of Haffkine's serum and of Lustig's and Galeotti's antitoxine. (*To be continued.*)

Kumyss Treatment and some Kumyss Settlements in Ufa.—P. V. Zesariévsky describes the advantages and disadvantages of various places in the Ufa province, where patients are sent to take the "kumyss cure."

Proceedings of Societies.

AMERICAN MEDICAL ASSOCIATION.

Fifty-second Annual Meeting, Held in St. Paul, on Tuesday, Wednesday, Thursday, and Friday, June 4, 5, 6, and 7, 1901.

The President, Dr. CHARLES A. L. REED, of Ohio, in the Chair.

General Session.

(Continued from page 1008.)

The Report of the Preliminary Committee on Reorganization.—Dr. J. N. McCormack, of Bowling Green, Ky., the chairman, presented a preliminary report which, after considerable discussion, was referred to a joint committee composed of the General Executive Committee

DR. FRANK B. WYNN,

Secretary of the Section in Pathology and Bacteriology.

and the enlarged Committee of Reorganization, which was made up of representatives from all the States.

The Report of the General Executive Committee.—Dr. S. L. Duncan Bulkley, of New York, called attention to the recommendation of the committee that the total number of papers presented at each of the various sections be limited to thirty-five. A motion was made and carried that hereafter the title of any paper which was unaccompanied by a brief abstract of the paper be omitted from the programme.

The Report of the Committee on National Legislation.—Dr. H. L. E. Johnson, of Washington, D. C., the chairman of this committee, reported that Senate bill No. 34, commonly known as the "Antivivisection bill," had been defeated in the Senate committee, and that it would probably be impossible to pass it.

DR. WILLIAM BRITT BURNS,

Secretary of the Section in the Practice of Medicine.

DR. R. R. CAMPBELL,

Secretary of the Section in Cutaneous Medicine and Surgery.

DR. J. A. LIPPINCOTT,
Chairman of the Section in Ophthalmology.

was none the less cordial for being twenty-four hours late.

The Army Canteen.—Dr. L. L. Seaman, of New York, introduced a resolution asking the association to petition Congress to reestablish the army canteen. The resolution caused considerable discussion. Some of the members argued that such action was not within the province of the association. It was finally referred to the committee on national legislation.

The Oration in Surgery was delivered by Dr. John A. Wyeth, of New York. (See page 984.)

The Report of the Committee on Reorganization.—The report of the joint committee on reorganization was presented by Dr. H. O. Walker, of Michigan, and was adopted after very little discussion. The new constitution provides for a House of Delegates, consisting of (1) delegates elected by permanently organized State and Territorial medical societies in affiliation with the American Medical Association; (2) two delegates elected by each of the component sections of the association; (3) one delegate each from the medical departments of the United States Army, the United States Navy, and the United States Marine-Hospital Service. The total membership of the House of Delegates shall not exceed 150. (To be continued.)

Section in Diseases of Children.

SYMPOSIUM ON TYPHOID FEVER IN CHILDREN.

(Continued from page 1016.)

The Dietetic Treatment of Typhoid Fever. By Dr. Louis Fischer.—In exhaustion: When the body loses large amounts of serum, the volume of the blood is so di-

minished, and the skin appears so parched and loses its normal elasticity, large quantities of water are indicated, and will be very grateful to the patient during the febrile stage. This deficiency of liquid may be supplied by injections of normal saline solution. The white of egg may be put into the water, and it is surprising to know how much albumin may be got into the body by this means. Whey is one of the favorite foods; it may be flavored with lemon juice or peppermint to make it more palatable. Barley water, rice water, farina water, and almond milk are all nutritious foods and easily digested and absorbed.

If toxæmia is profound, the author uses large injections of saline solution by hypodermoclysis, which should be given under the strictest antiseptic precautions. The lymphatics during the febrile stage are usually so greedy that they will absorb several quarts of this solution. The injections of normal saline solution should be repeated every six, twelve, or twenty-four hours, depending on necessity. If the stomach is very irritable and vomiting is an urgent symptom, the stomach should be given rest and rectal feeding resorted to. The rectum should be thoroughly flushed with a normal saline solution, and one ounce of thoroughly peptonized milk, to which one ounce of starch water is added, should be injected at intervals of every four hours. It is important to remember, too, that the raw white of eggs can be added to the saline solution and injected subcutaneously. Acidulated waters and carbonated waters seem to inhibit bacterial action as well as to be a grateful drink to the feverish patient. The successful management of typhoid fever depends, not upon the administration of drugs, excepting eliminatives, but solely on supporting the vitality of the child by giving it liquid foods, as above enumerated, and thus sustaining the heart.

The Treatment of Typhoid Fever, with Special Ref-

DR. E. C. ELLETT,
Secretary of the Section in Ophthalmology.

DR. HENRY P. NEWMAN,

Chairman of the Section in Obstetrics and Diseases of Women.

erence to the Intrarectal Injection of Normal Salt Solution. By Dr. E. Stuver.—Typhoid fever is an infectious disease caused by the entrance of the Koch-Eberth bacillus into the human body. The fæces is the principal medium by which it is conveyed to streams and other sources of water supply. In late years it has been demonstrated that the urine is also a source of great danger unless properly disinfected. In Gwyn's case they were found in the voided urine five years after the attack of typhoid. It is generally considered that the pathological lesions and general systemic manifestations of the disease, as well as the complications arising during its course, or following it as sequelæ, are not caused by the bacilli themselves, but result from the action of the toxins generated by them. These toxins penetrate every organ, tissue, and cell in the body, poisoning the brain and causing mental perversions, delirium, and other nervous derangements; poisoning the heart and producing muscular weakness, degeneration, and failure; and poisoning every cell in the body, thereby lowering vital resistance and deranging the secretory and excretory functions. The treatment should seek the cause of the trouble. First, inhibit or destroy the pathogenic microorganisms and neutralize or eliminate their poisonous toxins; secondly, strengthen the phagocytes and cells of the body and conserve the bodily forces. The patient should be put to bed at once and kept quiet, mentally and physically. The hygienic surroundings should be the very best, and the eliminative treatment, according to the author, holds a very prominent place. Calomel is given with sodium bicarbonate for the first few days until free catharsis is produced. The calomel is also a good diuretic and antiseptic, and not only inhibits the activity of the bacilli, but eliminates, and also arouses and strengthens, the lethargic phagocytes to action. The author employs the Woodbridge method of treatment. In addition,

he recommends a mixture containing carbolic acid and tincture of iodine, of each one third minim. He has also found good results from copper arsenite. The good effect of the antiseptic treatment is not a figment of the imagination, as some eminent men would have us believe, and the disease can be aborted, notwithstanding the medical nihilists who say that it cannot. If it is good treatment and hastens the healing process to drain and cleanse a wound on the surface of the body, why is it not equally good treatment to resort to similar measures in treating the infected, congested, and ulcerated bowel? The washing out of the alimentary canal lessens the number of the bacilli, decreases the amount of the accumulated toxins, and places the bowels in a vastly improved condition.

When the bowels act too freely, which only occurs in from ten to fifteen per cent. of cases, equal parts of the sulphocarbolates of zinc, lime, and soda have given good results. So soon as cardiac weakness makes its appearance, it is combated with a tablet containing nitroglycerin and the tinctures of digitalis, belladonna, and strophanthus. It has been generally believed that fever leads to fatty degeneration of the heart if the temperature is allowed to remain high for any length of time. Several years ago the coal-tar derivatives were extensively used. Happily, at the present time, safer and more rational views obtain, and these remedies, as well as the narcotics, are being relegated to a well-merited oblivion. The use of alcohol is pernicious, and its paralyzing influence reaches every organ, tissue, and cell of the body. It clogs the dialyzing membranes, interferes with the normal osmotic processes, retarding both assimilation and elimination, and the wonder is how it ever came to be so extensively used. It has always done harm. It irritates the heart, produces delirium, lessens excretion, and has a general bad effect. The cold bath is an ap-

DR. C. L. BONIFIELD,

Secretary of the Section in Obstetrics and Diseases of Women.

proved method of treating temperature and has many earnest advocates, so earnest, I have often thought, that they have failed to see the good in other methods of treatment. There is no question as to the good effects of the cold bath, but it is asserted, on the other hand, by Curtin and others, that the tendency to intestinal hæmorrhage is considerably increased by driving the blood from the skin, and thus congesting the internal organs.

Cold water *per rectum* has been advocated, but the use of the normal salt solution for this purpose is original. The injections are made with an ordinary fountain syringe. Sometimes they are not retained and come away, bringing some fæces with them, thus clearing out the bowel. When they are retained, however, the water passes out through the kidneys and the skin. Dr. William H. Thompson has ascertained that the use of normal salt solutions causes a marked increase in the amount of urine excreted and of the urea contained in it. If the

DR. ROBERT R. ANDREWS,

Chairman of the Section in Stomatology.

temperature is high, the solution is used cold, even ice-cold. Nervous irritability is reduced along with the fall of the temperature, toxines are eliminated from the system, and it prevents instead of causing internal congestion. Tympanitic distention, headaches, dierotic pulse and other evidences of profound toxæmia all disappear promptly. In the author's series of thirty-six cases treated with injections of normal salt solutions there was only one death. When the temperature was low, not exceeding 102° F., two ounces to a pint, according to the age and retaining capacity, was injected into the bowel every three or four hours. When it rose above this point, the injections were given every two hours. The patients sweated profusely and the kidneys acted freely. In none of the cases with high temperature was there delirium or abdominal tympanites, and the patients slept the whole

DR. ERNEST WENDE,

Chairman of the Section in Hygiene and Sanitary Science.

night through as peacefully as babies, even when the temperature was registering as much as 105.3° F. the next morning. In addition to the injections, plenty of cool water must be given to drink. It is to be seen that our

DR. J. N. HURTY,

Secretary of the Section in Hygiene and Sanitary Science.

DR. H. A. TOMLINSON,

Chairman of the Section in Nervous and Mental Diseases.

proper function is to use our efforts, not to reduce symptomatic fever, but to eliminate the toxins which cause the intestinal ulceration, the delirium and general toxæmia, and the various lesions and symptoms of the disease.

The diet is of the greatest importance. It should, I think, be liquid so long as there is an elevated temperature. The diet should be more liberal than was formerly given and the starvation process is opposed. As the proteids furnish an excellent culture medium for the bacilli the meats, meat broths, meat juices, etc., should not be given. Good fresh buttermilk is preferable to almost anything else. Sweet milk and cream may be given and lime water added will sometimes make it more tolerable and more easily borne, as well as more palatable to the patient. Whey, soft-boiled eggs, toast-water, barley-water, and fruit-juices and albumen-water have constituted the diet during the febrile stage. Care should be exercised during the convalescent stage to guard in every way against over-indulgence and imprudence in the diet.

Case of Multiple Gangrene Associated with Cholangitis Complicating Typhoid Fever. By Dr. I. A. Abt.—A female child, aged twenty-one months, came under observation on the fourth day of its illness. The father is at present ill in a hospital with typhoid fever. Examination on admission shows the tongue coated, the abdomen tympanitic, the spleen palpable and enlarged. The Widal reaction was positive, temperature 103° F., and there was slight œdema of the extremities. About ten days after admission furuncles appeared on the scalp and over the shoulder blade of the left side. After the child had been ill about two weeks, an eruption appeared on the back, neck, and extremities. At first, papules appeared; these became pustules and, in a very short time, areas of gangrene. Summing up the features of the skin the following are interesting points in the order of occur-

ence:—Red macules, papules, flaccid vesicles, and blebs. There were also pustulated or crusted papules, umbilicated vesicles, and ulcers with a dirty grayish moist slough. The ulcers have steep margins, are mostly oval in shape, and vary from the size of a split pea to that of a penny. The whole eruption impresses one as a multiple embolic process in the vascular system of the upper corium, leading to gangrene of the type called infectious multiple gangrene. The autopsy showed the gangrenous areas in the skin, which have been already described. The pericardial sac contained fluid. The myocardium was pale and flabby. The lungs were œdematous. The spleen was enlarged and showed the presence of infarcts. The kidneys examination was negative. The liver was large, light brownish in color, and distinctly soft. Over the entire surface there were a large number of whitish areas about the size of a pin. These were surrounded with a red border and were scattered irregularly throughout the organ. Microscopically, these areas are seen to be due to a necrosis of the parenchyma adjacent to the interlobular vessels. A study of these sections from the liver shows an inflammation of the bile passages, an angiocholitis. The liver also shows the presence of an adenoma. The author then proceeds with a critical review of the literature of multiple gangrene and typhoid fever.

The Treatment of Temperature by Drugs. By Dr. Edwin Rosenthal.—Collective statistics of typhoid fever in children have placed the mortality rate at or near five per cent. The thermometer retains the first place as a diagnostic implement. In young children, the febrile progress is often only from eight to fourteen days; the average course under ten years is 19.3 days. After the age of ten, this course is much like that of adults. Typhoid fever is perhaps the only disease in which the

DR. FRANK SAVARY PEARCE,

Secretary of the Section in Nervous and Mental Diseases.

DR. ELMER LEE,

Chairman of the Section in Physiology and Dietetics.

temperature runs higher in older than in younger children. If the fever is high and long continued, it will do much harm by its influence on the nervous system. If the temperature suddenly drops, it is of the same significance as in the adult—a case of hæmorrhage. If the fever continues longer than the average time, it is significant of a complication. A thorough knowledge of the febrile movement, its cause, and its dangers is as necessary as one of the drugs to be used. In the choice of remedies, one must use a surprising amount of common-sense judgment. The bad influence of too much drug treatment cannot be questioned. It is a misleading delusion to say that we can avoid it. Careful investigation proves that no special specific virtues can be designated; for this reason I cannot find one drug which has stood the test of time with an impartial judgment. While all the ordinary coal-tar derivatives have been thoroughly tried, none of them are allowable; and while they may influence the fever, that is, reduce its height, no particular virtue can be claimed for them. The same conclusion may be reached with regard to the Woodbridge treatment, which has proved to be a failure so far as limiting the disease is concerned. These so-called specific remedies, perhaps, have little or no influence. Quinine also proves perfectly inert; it does not influence the fever, and sometimes does more harm than good; in children it should never be used, though it has never shown that influence which the coal-tar products always exhibit. One must have a distinct understanding of the meaning of the fever in typhoid. The chief question is, not what drugs to use, but when is it necessary to interfere? It is conceded that the fever is but a protective reaction of Nature. A long-continued hyperpyrexia will produce tissue degeneration; that it will do it sooner in adults than in children is a well-known fact. Lacking the ideal way of interference, antitoxic serum,

Brandt's hydrotherapy is the next best thing. Other antipyretics, included in the line of drugs, which have been mentioned above, have only been mentioned to be condemned, since they possess no specific virtue.

Discussion.—Dr. Victor C. Vaughan drew attention to the fact of typhoid fever occurring less frequently in children than in adults, and explained this fact by the child's not getting around and drinking water from so many sources as an adult; for this reason, also, typhoid infection occurred less frequently in women than in men. It had also been said that typhoid fever occurred less frequently in pregnant women; cases of typhoid seemed to be less severe when the infection was a mixed one, for when there was a mixed infection with the colon bacillus an irritative diarrhoea was set up, which caused the intestinal canal to be regularly drained of its poisonous contents. Mixed infections were more likely to occur in the case of children; just why typhoid fever was milder in children was a question for which there was no positive explanation. The death rate seemed very hard to get at. In hospital practice it had been found to be eight or nine per cent.; but in a series of twenty thousand cases which were selected the death rate was between sixteen and seventeen per cent. In children, perhaps, the reason for a lower death rate might possibly be found in the better elimination through the skin, kidneys, and other organs of toxic products. It was high time to stop experimenting with drug antipyretics. If these dangerous drugs were to be used, let us make our experiments on animals and not on human beings. The only way to reduce temperature was by the cold bath. The occurrence of multiple gangrene was an exceedingly interesting matter, and had been found in malaria, smallpox, etc., as well as in typhoid. The fact of being able to diagnose these things by a positive discovery of the bacillus gave us now a clearer insight into the disease.

DR. R. HARVEY COOK,

Secretary of the Section in Physiology and Dietetics.

Dr. Clifton Scott referred to the view held by some that cold baths caused internal congestion, but had not found it so in his experience.

Dr. Charles Douglass found the medicinal treatment of typhoid fever very unsatisfactory; temperature might be controlled entirely by the baths and proper regard to the diet. The diet should always be kept down to the point where there was perfect digestion, then both less baths and less medicine are necessary. He did not agree with the popular idea with regard to the use of calomel in small doses; his experience was that cases which were allowed to preserve quiet bowels continued to a steady recovery; the temperature went steadily down without purgation if proper care was used in the diet. Feeding should be such as to make the stools normal in character and free from any bad odor. Odor, color, and consistency of the stools were the things to guide in the feeding. Anything might be given to the patient that he could properly digest; milk, broths, the white of eggs, and starch water might all be given if the quantity was regulated in accordance with the conditions present. Abdominal complications and tympanites gave no trouble where this was looked after, and patients might frequently go from one to seven days without a movement from the bowels, and no bad effects follow. Calomel or other forms of purgation were not necessary if the diet was steadily cut down, when the bowels usually took care of themselves.

Dr. F. Wood thought we frequently fed our typhoid patients too much; less food, less medicine and more water gave better results than over-feeding; it was very important to provide perfect quiet for these cases; they should not be allowed to become restless, to talk too much, or be bothered, or urged to eat at all unless they wanted to eat. Oftentimes injudicious use of milk would cause tympanites. If hæmorrhage occurred, perfect quiet should be maintained by the use of morphine. Quiet was more important in this complication than any medicine.

Dr. Head pointed out the great value of the leucocyte count as an aid to the diagnosis between meningitis and some of those forms that came on like appendicitis.

(To be continued.)

Book Notices.

A Text-book on Practical Obstetrics. By EGBERT H. GRANDIN, M. D., Gynæcologist to the Columbus Hospital, etc. With the Collaboration of GEORGE W. JARMAN, M. D., Instructor in Gynæcology in the Medical Department of Columbia University, etc. Third Edition, Revised and Enlarged. Illustrated with 52 Full-page Photographic Plates and 105 Illustrations in the Text. Pp. xiv-511. Philadelphia, New York, and Chicago: The F. A. Davis Company, 1901. [Price, \$4.]

THE third edition of this work appears in one volume instead of in two, as formerly. Several emendations have been made and the chapter on the anatomy of the female generative organs has been revised and enlarged. As its title implies, the work is essentially a practical one, and it is no doubt largely due to this element that the book has had the success which it has enjoyed. The clear text and the excellence of illustration render the work specially valuable to the student and to the general practitioner. We have before spoken of the first illustration on Plate xxxiv as worthy of being re-

placed by one in which the resuscitating doctor shall appear, at least, to be less apprehensive of the outcome of his efforts. In all other respects the good words spoken in behalf of former editions of this work remain true.

Bibliographie générale des travaux parus sur lait et sur l'allaitement jusqu'en 1899. Par le Dr. HENRI DE ROTHSCHILD, Lauréat de la Faculté de Médecine. Avec une préface de M. E. DUCLAUX, Directeur de l'Institut Pasteur. Pp. xii-584. Paris: Octave Doin, 1901.

IN this large volume the author has collected all literary references to milk and the artificial feeding of infants published since 1889. All modern languages are represented and the references run deep into the thousands. To those interested in the subject, the book will form an invaluable reference work.

Human Placentation. An Account of the Changes in the Uterine Mucosa and in the Attached Fœtal Structures during Pregnancy. By J. CLARENCE WEBSTER, B. A., M. D. (Édin.), F. R. C. P. E., F. R. S. E., Professor of Obstetrics and Gynæcology in Rush Medical College, etc. Pp. 126. With 233 Illustrations. Chicago: W. T. Keener & Company, 1901.

IN this monograph Dr. Webster has done a good service. In the first place, it is a thorough study of the development of the human placenta from the first month of pregnancy up to its departure from the uterus at full term. Secondly, it gives, in concise form, the phylogeny of placentation; and, most important of all, the studies on the syncytium will tend to throw some light upon the still vexed question of malignant deciduoma. Fatty degeneration in a normal placenta is held to be not proved. Infarcts of the after-birth are clearly, but briefly, described. The absorption of the decidua is carefully studied, and the various appendices of the placenta are minutely figured in their development and evolution. To those who are interested in embryology, no less than to those who care for physiology and pathology, Dr. Webster's book, despite the slight lapses in bookmaking, will prove indispensable. The thirty plates accompanying the text are admirably executed.

Miscellany.

Somnolency in Liver Disease.—The *Canadian Journal of Medicine and Surgery* for April says that ever since Murchison's investigations, observers have noted the possibility of somnolency arising *ab hepate læso*; but this origin is considered rare and of little moment, except in extreme cases, such as coma or narcolysis. Gilbert and Castaigne, however, have reported to the Paris Society of Biology, on October 27, 1900, that simple somnolency is one of the commonest symptoms of some forms of cholæmia, particularly angeiocholitis and hypertrophic biliary cirrhosis. This somnolency is not due to hepatic insufficiency, as has been generally held, these observers having proved the contrary by a study of the chemistry of the biliary secretions of their patients. They think that the somnolency is due to a biliary intoxication, acting on a predisposed nervous system.

The Origin of Eczema.—Dr. C. F. Marshall (*Treatment, March*) sums up an article on this subject with the following conclusion:

"It appears to me that we can only come to one rational conclusion, after the consideration of the above

evidence, viz., that eczema is not of parasitic origin, but is due to disordered metabolism, giving rise to irritating substances in the blood, probably uric acid, or one of the substances into which it becomes decomposed. The parasitic theory does not explain the frequently universal and rapid appearance of acute general eczema so well as the autotoxic theory. Again, acute general eczema often subsides in a remarkably rapid way under soothing remedies which contain no parasiticides. Tommasoli's view appears to be the most rational which has appeared lately, and stands out as an oasis in the vast desert of parasitic literature, which would appear to regard the skin as something quite distinct from the rest of the human body."

Medicine in Thibet.—Dr. Susie Carson Rijnhart, in her book, *With the Thibetans in Tent and Temple*, says that there is no medical art worthy to be called such in Thibet. She writes:

"For headache, large sticking plasters are applied to the patient's head and forehead; for rheumatism, often a needle is buried in the arm or shoulder; a tooth is extracted by tying a rope to it and jerking it out, sometimes bringing out a part of the jaw at the same time; a sufferer with stomach-ache may be subjected to a good pounding, or to the application of a piece of wick soaked in burning butter grease, or, if medicine is to be taken internally, it will consist probably of a piece of paper on which a prayer is written, rolled up in the form of a pellet, and, if this fails to produce the desired effect, another pellet is administered composed of the bones of some pious priest."

The Physical Evils of Eating Alone.—Under the heading, *The Indigestion of Loneliness*, the *Lancet* for May 25th makes the following cogent remarks, which probably apply with even greater force in this country than in England. The *Lancet* says:

"At a time like the present, when the marrying age of the average man of the middle classes is being more and more postponed, the physical ills of bachelorhood come increasingly under the notice of the medical man. It is not good for man or woman to live alone. Indeed, it has been well said that for solitude to be successful a man must be either angel or devil. This refers, perhaps, mainly to the moral aspects of isolation, and with these we have now no concern. There are certain physical ills, however, which are not the least among the disadvantages of loneliness. Of these there is many a clerk in London, many a young barrister, rising, perhaps, but not yet far enough risen, many a business man or journalist, who will say that one of the most trying features of his unmarried life is to have to eat alone. And a premature dyspepsia is the only thing ever takes him to his medical man. There are some few happily disposed individuals who can dine alone and not eat too fast, nor too much nor too little. With the majority it is different. The average man puts his novel or his paper before him and thinks that he will lengthen out the meal with due deliberation by reading a little with, and more between, the courses. He will just employ his mind enough to help, and too little to interfere with, digestion. In fact, he will provide that gentle mental accompaniment which with happier people conversation gives to a meal. This is your solitary's excellent idea. In reality he becomes engrossed in what he is reading till suddenly finding his chop cold he demolishes it in a few mouthfuls; or else he finds that he is hungry and paying no attention to the book, which he

flings aside, he rushes through his food as fast as possible, to plunge into his armchair and literature afterward. In either case the lonely man must digest at a disadvantage. For due and easy nutrition food should be slowly taken and the mind should not be intensely exercised during the process. Every one knows that violent bodily exercise is bad just after a meal, and mental exertion is equally so. Wise people do not even argue during or just after dinner, and observation of after-dinner speeches will convince any one that most speakers neither endure themselves nor excite in their hearers any severe intellectual effort. In fact, the experience of countless generations, from the Red Indian of the woods to the white-shirted diners of a modern party, has perpetuated the lesson that a man should not eat alone, nor think much at this time, but should talk and be talked to while he feeds. Most people do not think much when they talk, and talking is a natural accompaniment of eating and drinking. How does it fare with the many solitary women of to-day? No better, we know, than with the men, but differently. Alone or not, a man may generally be trusted at any rate to take food enough. (We suppose, of course, that he can get it.) With a woman it is different. She is more emotional, more imaginative, and less inclined to realize the gross necessities of existence. Therefore the woman doomed to dine alone as often as not does not dine at all. She gets dyspepsia because her digestion has not sufficient practice; a man gets it because his functions practise it too often in the wrong way. Worst of all, perhaps, is the case of the solitary cook. In the myriads of small flats in London there are thousands of women 'doing' for their solitary masters or mistresses. These women, whose main occupation is to prepare food for others, find it impossible to enjoy, or even to take, food themselves. As confectioners are said to give their apprentices a free run of the stock of the shop for the first few days, knowing that it will effectually cure appetite afterward, so the women who are always occupied with buying and preparing food grow unable to use it for themselves. These people suffer from dyspepsia, which is cured if somebody else manages their kitchen for a week, allowing them to take meals without preparing them. It needs no moralist to declare the evils of solitariness. Man and woman is a gregarious animal. Physically and intellectually we improve with companionship. Certainly it is not good to eat and to drink alone. It is a sad fact of our big cities that they hold hundreds of men and women who in the day are too busy and at night too lonely to feed with profit, much less with any pleasure."

St. Paul's Prescription for the Physicians.—The *St. Paul Pioneer Press* for June 4th has a cartoon showing an anything but ascetic St. Paul, with a nimbus of modern construction worked by an incandescent light, presenting to "the M. D.'s" a large bottle of medicine labeled "Welcome," with the words, "Take three big doses of this every day, in water or something else." St. Paul did more than prescribe; it provided the medicine as well as the "something else" to take it in—the expi-ent—and, what is more, saw that it was taken.

Heroic Measures Needed.—*Punch* for May 8th gives the following: *Doctor*—"Well, you got those leeches I sent for your husband, Mrs. Giles?" *Mrs. Giles*—"Yes, zur; but what on earth be th' good o' sending the little things for a girt big chap like he? I jcs' took an' clapped a ferret on 'un!"

Special Articles.

SYPHILITIC FEVER,
WITH A REPORT OF THREE CASES.

(From the Service of Professor William Osler.)

By THOMAS B. FUTCHER, M. B.,

BALTIMORE,

ASSOCIATE IN MEDICINE, THE JOHNS HOPKINS UNIVERSITY;
RESIDENT PHYSICIAN, THE JOHNS HOPKINS HOSPITAL.

WHILE its protean characters are universally recognized, physicians do not sufficiently appreciate the fact that syphilis is often responsible for many cases of obscure fever, which clear up only when proper antisyphilitic treatment has been instituted. Even when the fever is associated with a recognizable syphilitic lesion it is often attributed not to the syphilitic infection, but to some other cause, and treated accordingly. The cases, however, which most frequently give rise to an error in diagnosis are those in which at the time there is no outward manifestation of the disease, and where the primary syphilitic infection, with possibly secondary or tertiary symptoms, has occurred so long before that its bearing on the fever is lost sight of. Many cases of syphilitic fever, being unrecognized, are treated as one or other of the acute infectious diseases. The treatment being ineffectual, a more careful physical examination of the patient reveals, possibly, a slight thickening of the clavicles or tibiæ or some evidence suggestive of visceral syphilis. Suspicions are then aroused that the fever may be of specific origin and antisyphilitic treatment is begun with a prompt return of the temperature to normal. That this late syphilitic fever is not sufficiently recognized is shown by the fact that few of the writers on syphilis refer to it. Rarely is it mentioned in text-books, though both Osler (1) and Musser (2) emphasize the importance of bearing it in mind in fevers of obscure origin. The purpose of this paper is to draw attention to this interesting symptom and to report a few cases of syphilitic fever which have been admitted to Dr. Osler's wards in the Johns Hopkins Hospital.

Syphilitic fever may occur at various periods during the course of the infection.

1. It may occur, in very rare instances, so long as three or four weeks before the onset of the secondary skin eruption. This early fever is puzzling and is likely to be attributed to some other cause until the eruption makes its appearance.

2. It may precede or be coincident with the appearance of the secondary eruption. This is the so-called "fever of invasion," and it is a very common and important symptom of secondary syphilis.

3. The fever may occur at any time during the course of the secondary or tertiary stages. The late occurrence of the fever is a most interesting feature. In Case III, for instance, it occurred twenty-nine years after the disease was contracted.

The "fever of invasion" is rarely absent at the onset of the secondary symptoms. It is sometimes wanting, however. It usually precedes the appearance of the secondary eruption by a week or ten days. Rarely does it antedate the eruption by more than two weeks. Practically all authorities now agree that this fever is a symptom of the invasion of the system by the organism believed to be the cause of syphilis or by its toxic products. At an earlier date some observers were inclined to attribute it to some coincident infection. At the onset of the fever there is often a transitory erythema of the skin which disappears, to be followed by the true syphilitic roseola a few days later. Lang (3) states that the fever of invasion is seldom ushered in by a chill. It is usually accompanied by headache, malaise, general depression, and rheumatoid pains throughout the body, which are most annoying in the afternoon. The height of the fever varies greatly in different cases. It may only be moderate, not reaching above 101° F. On the other hand, the daily elevation may be much higher, the afternoon temperature reaching as high as 104° F. to 105° F. Lang quotes Stoll as authority for the statement that the fever of invasion in syphilis is usually of a definite remittent type, and states that all syphilologists who have studied this symptom of syphilis agree on this point. All cases do not conform to this rule, however. The fever of invasion, as well as the syphilitic fever associated with the late manifestations of the disease, may present any one of the following three clinical types of fever:

1. A mild continuous pyrexia, where the temperature ranges in the neighborhood of 101° F. Osler states that this type is not uncommon in the fever which ushers in the constitutional symptoms.

2. A remittent type of fever, with morning drops toward normal and evening exacerbations. This, as already stated, is considered the usual character of the fever of invasion.

3. A definite intermittent fever. This is the most remarkable form of all and is the type which is most likely to lead to error in diagnosis.

Syphilitic fever, although usually a secondary manifestation, may occur late in the disease. The febrile diseases for which such a fever is only too often mistaken are malarial fever, typhoid fever, tuberculosis, and sepsis. Where general pains and joint-pains accompany the fever, the diagnosis of rheumatism may be made.

The following case was one of unusual interest and illustrates how puzzling some of the cases of syphilitic fever may be during the period of the fever of invasion:

CASE I (Hospital No. 32480).—*Syphilitic fever of remittent and intermittent type, commencing at least twenty-seven days before the appearance of the secondary eruption. Fever ushered in by a chill, followed by sweating.*

L. B., a woman, married, aged thirty-four years, was admitted to the gynæcological department of the Johns Hopkins Hospital on September 28, 1900, complaining

of abdominal pain. The family and personal histories then obtained were unimportant.

The abdominal pain of which the patient complained on admission began three weeks before she entered the hospital. The night before admission she had a shaking chill, followed by a profuse sweat. The patient was examined by Dr. G. B. Miller, who found a pelvic abscess, with evidences of a double salpingitis. On September 29th and 30th the temperature ranged between 98.7° F. and 101° F. This fever may quite possibly have been due to the local pelvic inflammation. On October 1st the pelvic abscess was evacuated *per vaginam* by Dr. Miller. The temperature failed to drop, and on October

of temperature, commencing on October 9th and lasting until October 11th, the temperature reaching 104.2° F. on October 10th. On October 14th a fourth febrile attack occurred, the temperature rising to 103° F. From this time on, the temperature gradually fell, but there were still slight elevations of temperature in the evening.

The case naturally occasioned a great deal of worry. It was thought that there might still be a focus of suppuration in the pelvis. Pelvic examination showed the local condition to be perfectly satisfactory, and no pus focus could be found. The heart and lungs were normal. There were no rose-spots. The leucocytes were frequently counted and were practically normal throughout, the

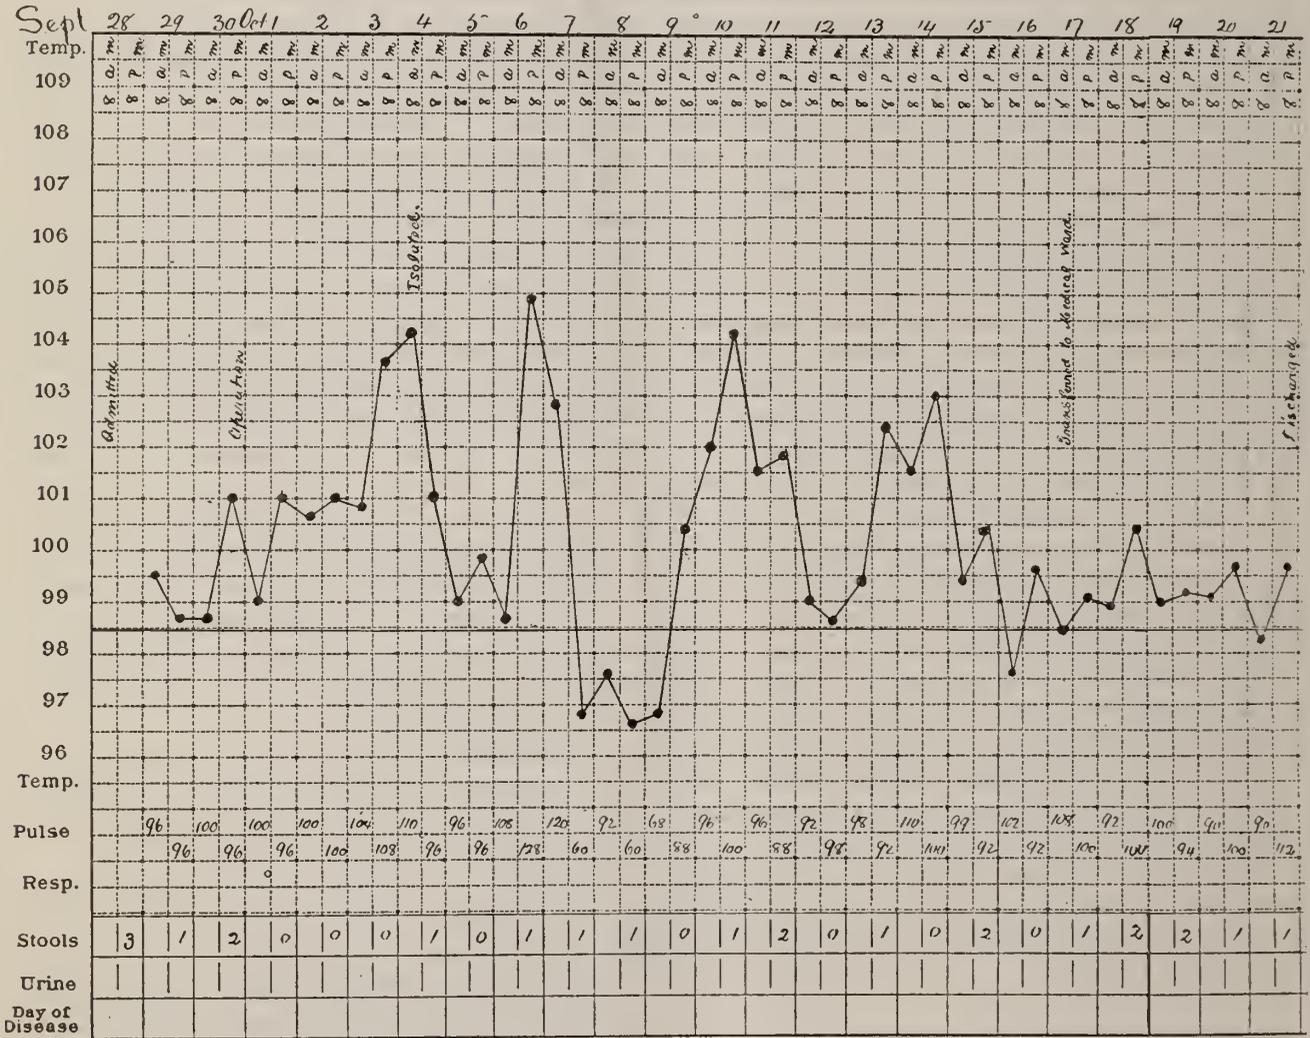

Chart I.—Case 1, L. B., Syphilitic Fever.

4th it rose to 104.2° F. (see Chart I). On this date there was a slight erythema of the skin of the body. As it was thought possible that one of the acute exanthemata was developing, the patient was transferred to the isolation ward. The erythema proved transitory, however, and had disappeared by the following day. This febrile paroxysm, on October 3d and 4th, was ushered in by a definite chill and accompanied by profuse sweating. The temperature fell very slowly and had not reached normal before another febrile attack occurred on October 6th, the temperature rising in the evening to 105.5° F., falling rapidly and reaching normal at midday on October 7th. Subsequently, there was a third exacerbation

highest count at any time being 10,000. The spleen was distinctly palpable, and it was thought possible that the case might be one of atypical typhoid fever. The Widal tests proved negative. The character of the fever suggested strongly an æstivo-autumnal malarial infection, but repeated examinations of the blood failed to show any malarial parasites.

On October 17th the patient was transferred to the medical service of the hospital, there being no further indication for isolation and it having been decided that the fever was not due to any pelvic complication. The physical examination of the patient, however, failed to throw any light on the obscure fever from which the pa-

tient had suffered. The patient was feeling much better in every way and, as the temperature was elevated only about one degree each day, she was discharged on October 21st, apparently practically well. There was no evidence of any skin eruption when the patient left the hospital. The provisional diagnosis was "intermittent fever of doubtful origin."

The subsequent history of the case was of great interest and clearly explained the cause of the obscure fever. On October 30th the patient returned with a definite macular and papular secondary syphilitic eruption, the diagnosis being confirmed by Dr. Gilchrist. On November 4th, when she again returned for observation, the face, shoulders and arms presented a definite macular eruption, and over the front and back of the chest there were scattered papules and an occasional pustule. There was general enlargement of the superficial lymph glands, the epitrochlear glands being the size of hickory-nuts.

Inquiry was now made into the venereal history of the patient's husband. He admitted exposure to infection on July 4, 1900. On August 11th he came to the Johns Hopkins Hospital Dispensary for treatment, and the records show that he then had a hard chancre on his penis. On August 27th he returned with a macular syphilitic eruption, and again, on September 15th, he was treated for a gonorrhœal urethral discharge.

On questioning the patient, she could give no history of the onset of the primary sore, nor were there any evidences of a chancre made out at the time of the operation, although it was not specially looked for.

The points of interest in this case are: (1) The impossibility of establishing a diagnosis until the secondary skin eruption became manifest; (2) the occurrence of chills and sweating and the close resemblance of the fever to that of æstivo-autumnal malaria; (3) the absence of any definite relationship between the fever and eruption which did not appear until practically four weeks after the onset of the fever; (4) the subsidence of the temperature to nearly normal a considerable time before the appearance of the skin eruption and without antisiphilitic treatment.

A case very similar to the above has been reported by Burney Yeo (4). The patient had a fever ranging as high as 104° F. to 105° F., with daily oscillations of from 5 to 6 degrees. An interesting feature of his case was that the fever began between twenty-five and thirty days after exposure, and between three and four weeks before the appearance of the secondary eruption.

CASE II (Hospital No. 10581).—*Syphilitic fever of a remittent and intermittent type which for weeks was suspected of being typhoid fever and treated as such. Diagnosis established by the discovery of periosteal thickening over the clavicles and by cessation of the fever after the beginning of treatment with potassium iodide.*

N. R., a man, married, aged thirty-nine years, was admitted to Dr. Osler's service in the Johns Hopkins Hospital on August 8, 1894, complaining of pains all over the body. The family history was unimportant, with the exception that his father had died of pulmonary tuberculosis. The patient had always been a healthy man. He had had gonorrhœa, but denied ever having had lues. He used alcohol in moderation.

The patient had been ill and unable to work for three

weeks previous to admission. During this period he had felt feverish at times. Nausea, vomiting, and diarrhœa were complained of during the week previous to his entering the hospital. He had not had headache or epis-

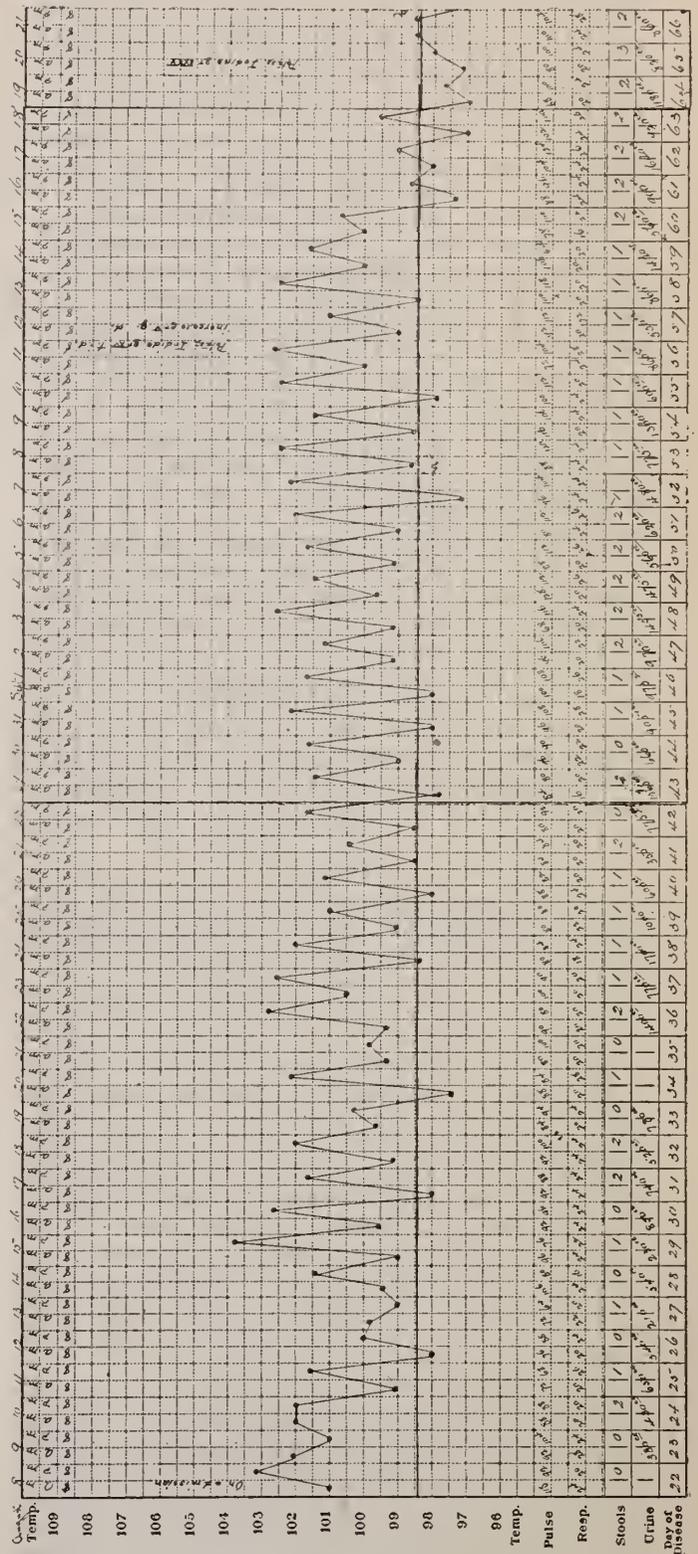

Chart II.—Case 2, N. R.

taxis, but had complained of aching pains in the back and extremities and of general weakness. There had been a steady loss in weight, but the patient had not been confined to bed previous to admission.

The physical examination of the patient failed to reveal anything to account for his fever and other symptoms. There was a corneal opacity of the right eye, which, however, was believed to be due to perforating corneal ulcer occurring during childhood. The examination of the thoracic organs was negative. There were no typhoid rose-spots. The liver was not enlarged, but the spleen was palpable four centimetres below the costal margin. The superficial glands were not enlarged. There were several pigmented scars on the right shin, but there were no nodes on either tibia. The blood examination was negative for malarial parasites. The urine was normal and did not show the diazo reaction.

As already stated, the patient apparently had irregular fever for three weeks previous to admission. On the day he entered the hospital his temperature rose to 103.4° F. at 8 P. M. The pulse and respirations at the same hour were 92 and 20 to the minute. A two-hour temperature record was taken and, from August 8th to September 12th, there was persistent fever. At times the temperature ran a fairly continuous type, but usually was remittent or intermittent in character, the evening exacerbations reaching as high as 102° F. to 103° F. Chart II, which records the 8 A. M. and 8 P. M. temperatures, gives a fair idea of the character of fever in this case, but fails to show the highest and lowest temperatures on certain days. Owing to the fact that the patient was admitted to the hospital at a season when typhoid fever was prevailing, and, taking into consideration the character of the fever and the enlargement of the spleen, it was strongly suspected that the case was one of typhoid fever, and the patient was given cold sponges. The diagnosis was always in doubt, however. At no time did rose-spots appear, and the urine never gave the diazo reaction. The case occurred before the Widal reaction came into use.

On September 12th Dr. Thayer made the following note: "Both clavicles toward their sternal ends are remarkably thickened and bowed. They feel remarkably as if the thickening were due to an old periosteitis. Both ulnæ and tibiæ are free from nodes. There is a distinct scar on the glans penis, and the patient says that he had a sore on the prepuce."

It was thus suspected for the first time that the fever might be of syphilitic origin. Accordingly, on September 12th, potassium iodide in fifteen-grain doses three times a day, was begun, the amount being gradually increased from day to day. The effect on the temperature was most striking. On September 13th there was practically no change, the temperature reaching 102.4° F. at 8 P. M. From this day on it steadily fell, reaching normal on September 16th, four days after the potassium iodide was started. It remained normal during the rest of his stay in the hospital. He was discharged from the hospital on October 3d, feeling perfectly well.

The day the patient left the hospital Dr. Osler made the following note: "This case is of exceptional interest in connection with the fever of lues. Although he had no rash, no visceral lesion, only chronic periosteitis of the clavicles, which are now symmetrically enlarged, the history of lues, the presence of the periosteitis, and the drop in the temperature after specific treatment was started, seem to justify the suspicion if not conclusion that this case is one of luetic fever."

This case illustrates very well how closely some cases of syphilitic fever resemble typhoid fever, both in the clinical symptoms, and to a less degree in the character

of the temperature. It also shows the importance of carefully examining the condition of the long bones in fevers of doubtful origin, for in this patient the cause of the fever was determined by the discovery of periosteal thickening of the clavicles. Prentiss (5) published a similar case of syphilitic fever with remittent temperature, in which typhoid fever was first considered. The presence of a pharyngitis and the development of a suggestive-looking ulcer over the right tibia led to the suspicion that the patient was probably suffering from syphilis. Treatment with potassium iodide and mercury was followed by an immediate return of the temperature to normal.

CASE III (Hospital No. 5796).—*Syphilitic fever, characterized by intermittent chills with fever, and treated first as a case of malaria. Fever occurred twenty-nine years after the primary infection and yielded readily to antisyphilitic treatment.*

W. W., single, man, a physician, aged fifty-seven years, was admitted to the Johns Hopkins Hospital in Dr. Osler's service on August 24, 1892, complaining of having suffered from chills and fever. He had had typhoid fever at fourteen, and diphtheria at twenty-eight years of age. In 1864, at the age of twenty-eight years, he contracted syphilis and developed definite secondary symptoms. Later, he had deep ulcers on his body which were apparently tertiary lesions. These persisted for three years, but eventually yielded to mercury and potassium iodide. In 1882, while in good health, a sore developed in the popliteal space and another in the hairy scalp. He again took specific treatment and the lesions cleared up.

About June 15, 1892, several sores appeared on his body, which, from the description given, were apparently rupial in character. About two weeks before admission to the hospital some tenderness and swelling developed over the sternum and in the left shoulder-joint. About the end of July the patient began to have definite recurring attacks of chills and fever, the temperature rising to from 102° F. to 104° F. The physician in attendance thought that the chills were of malarial origin and gave quinine in daily doses of twenty grains, without any effect on the fever. A few days before the patient entered the hospital Dr. Osler saw him in consultation. A definite history of recurring chills was obtained, but the examination of the blood showed no malarial parasites. The fever was regarded as probably of luetic origin, and potassium iodide in increasing doses was begun. When the patient entered the hospital a few days later, on August 24th, the chills had ceased, but he was still having evening elevations of temperature to 101° F. Under the iodide the temperature gradually fell, and by September 14th reached normal and did not become elevated afterward. The patient remained in the hospital until November 2, 1892, on which date he was discharged, feeling perfectly well.

The case just related illustrates the error so often made of mistaking syphilitic fever for malaria. The late occurrence of the fever, namely twenty-nine years after the syphilis was contracted, is of great interest. This is a longer period after infection than in any case of which I have been able to find records in the literature. A remarkable case of syphilitic fever is reported by Sid-

ney Phillips (6). His patient, a woman, had regular intermittent chills, fever and sweating occurring every other day over a period of eight months. Early in the illness the paroxysms occurred daily, but later presented a typical tertian intermittent type, and the fever was practically identical with that of tertian malaria. Quinine was given a thorough trial, without any effect on the temperature. The fever began to fall very soon after the beginning of the administration of iodide of potassium and reached normal in a few days. In this case the fever occurred nine years after the syphilis was contracted.

Syphilitic fever is mistaken for tuberculosis even more frequently than for malaria. The patients may present themselves complaining of fever, sweating at night, loss of weight, general malaise, and possibly some pain in the chest. The examination of the lungs may show a few râles, which renders the case very suspicious. In other instances the diagnosis is made without any signs in the lungs or elsewhere in the body pointing to tuberculosis. Janeway (7) has drawn especial attention to the prevalence of this error in diagnosis. He points out that the mistake is not made alone by physicians of little experience, but often by those of well-established reputation. In a most interesting paper he cites six cases of syphilitic fever which had been interpreted and treated as tuberculosis. The cases had subsequently come under his personal observation. Four of these had been sent to health resorts for phthisical patients without benefit. Careful examination and inquiry into the history of each case led to a diagnosis of syphilis, with prompt disappearance of the fever and restoration of the health of the patient after the commencement of specific treatment. Morgan (8) reported a case of syphilitic fever of intermittent type, in which acute miliary tuberculosis was for a considerable time suspected. The absence of tubercle bacilli from the sputum and the existence of a luetic history led to the administration of potassium iodide, with prompt recovery from the symptoms and cessation of the fever.

Other cases of syphilitic fever could be cited, but the three cases reported above suffice to draw attention to the main points of interest in the consideration of this interesting symptom of lues.

The following points may be emphasized in connection with syphilitic fever:

1. In all cases of fever of obscure origin the possibility of it being syphilitic should be borne in mind.
2. Experience has shown that physicians of reputation, as well as those of limited experience, are prone to mistake the condition for one of the acute specific fevers.
3. The affections for which syphilitic fever is most often mistaken are malaria, typhoid fever, tuberculosis, sepsis, and occasionally rheumatic fever.
4. The fever may occur as early as four weeks previous to the appearance of the secondary skin eruption, or, what is of greater importance, late in the disease after tertiary manifestations have existed probably for years.

In Case III it occurred twenty-nine years after the primary lesion.

5. The fever may be continuous, remittent, or intermittent. The remittent type is regarded as the most frequent form in the fever of invasion. The fever is often associated with chills and sweating.

6. Careful examination of the long bones and viscera for evidences of tertiary lues should be made in all cases of fever of obscure origin.

THE EVOLUTION OF THE OPHTHALMOSCOPE AND WHAT IT HAS DONE FOR MEDICINE.*

By SAMUEL THEOBALD, M. D.,

BALTIMORE,

PRESIDENT OF THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND; CLINICAL PROFESSOR OF OPHTHALMOLOGY AND OTOTOLOGY, JOHNS HOPKINS UNIVERSITY.

IN casting about for a theme for the annual address which is expected of your presiding officer, it occurred to me that as this year, 1901, is the fiftieth anniversary of the invention of the ophthalmoscope, it would not be amiss to give you to-day a brief account of this event, fraught, as it was, with such momentous consequences to ophthalmology, and to describe the steps by which the ophthalmoscope, as we now know it, has been gradually evolved from the primitive instrument with which Helmholtz first succeeded in seeing the back-ground of the living eye.

As has so often happened with important discoveries and inventions, Helmholtz's contrivance of an *Augenspiegel* with which to inspect the interior of the eye, first described in a monograph published in Berlin, in December, 1851 (1), seems to have been but the logical outcome of a series of interesting observations made by a number of investigators in the field of physiological optics. But, oddly enough, the problem which these in-

*An address delivered before the Medical and Chirurgical Faculty of Maryland at the opening of its one hundred and third annual session, held in Baltimore, April 23, 24, and 25, 1901.

investigators, with the exception of Cumming, were endeavoring to solve, and which Helmholtz himself had in mind, was not the discovery of a means by which the back-ground of the eye could be inspected and pathological changes situated there recognized, but a solution of the question why, under usual conditions, the pupil of the eye appears black and seems to emit no light, while, under certain unusual conditions, it does emit light and assumes a reddish appearance.

The luminosity of the eyes of certain animals had long been a subject of study, and many erroneous theories had been advanced to account for it; but not until Prévost, of Geneva, about 1810, pointed out that in an absolutely dark room the luminosity disappears, was it understood that this phenomenon was due simply to the reflection, from the tapetum, of light which had entered the eye through the pupil. Rudolphi made a further step toward a right understanding of the matter when he showed that, in order to perceive these reflected rays, it was necessary to look into the eye in a certain determinate direction.

Behr, in 1839, as a result of his study of a case of total irideremia, or absence of the iris (in which condition, as is well known, the pupil often presents a reddish appearance), announced that to obtain this effect the observer must look into the irideremic eye in a direction parallel to the rays of light incident upon it. Long before this, the fact that in certain pathological conditions of the interior of the eye, such as intra-ocular growths and detachment of the retina, the pupil appears grayish instead of black, had attracted attention.

Still more important, however, and bearing more directly upon Helmholtz's invention, were the investigations and observations of William Cumming and Ernst Wilhelm Brücke. At about the same time, and without knowledge of the other's labors (2), each of these investigators had succeeded, and by similar methods, in obtaining a reflex from the back-ground of the normal human eye.

Cumming, at the time a student in the London Hospital, presented his observations in a paper read before the Royal Medical and Chirurgical Society of London, June 23, 1846, and published in the *Transactions* of the society for that year (3). The title of his paper is On a Luminous Appearance of the Human Eye, and its Application to the Detection of Disease of the Retina and Posterior Part of the Eye.

The luminous appearance or reflection was obtained by placing the person whose eye was to be examined in a dark room, at a distance of ten or twelve feet from a gas or other bright light. A screen being so placed as to cut off the lateral rays, the more direct ones were permitted to fall upon the face and eye of the observed, while the gaze was directed a little to the side of the light. The eye of the observer being now brought as near as possible to the direct line between the light and the eye to be viewed, caught certain of the rays reflected from the

back-ground of the latter, and the pupil assumed a red appearance. A similar result, Cumming pointed out, could be obtained by a beam of daylight admitted through a nearly closed shutter. He noted, with interest, that sometimes, in consequence of a slight movement of the observed eye, the red color of the pupil changed to a silver tint, an effect, doubtless, due to the fact that at this moment his eye caught the rays reflected from the white surface of the optic disk. He at first supposed that the light which gave the luminous appearance to the pupil was reflected from the retina; but later became convinced—Mr. Bowman having first suggested this to him—that it was the chorioid which caused the reflection. Feeling that he had established the principle that in normal eyes a luminosity of the pupil could always be obtained by the method he had devised, he maintained that where this could not be done an abnormal or pathological condition of the interior of the eye existed; and in support of this contention he related several cases examined by him at the Royal London Ophthalmic Hospital, one of which, from the description given, was, in all probability, a case of lateral detachment of the retina. When, further, he attempted by the help of his discovery to recast the subject of what was then known as "cat's-eye amaurosis," it is not surprising that he should have got the subject, as well as himself, in something of a muddle.

The observations of Brücke, who was professor of physiology in Vienna, were published in Müller's *Archiv für Anatomie und Physiologie*, in 1847. Besides obtaining a reflex from the fundus of the eye by a method similar to that employed by Cumming, Brücke secured, doubtless, a still better illumination of the pupil by placing a tube through the flame of a candle and looking through this directly into an eye upon which the light from the candle was permitted to fall. He also described a significant observation of his friend, Dr. von Erlach, who, being myopic and wearing concave glasses, had remarked upon several occasions that the light reflected from his glasses caused the pupils of a person standing in front of him to emit an unusual glow. The peculiar significance of this observation of von Erlach's, which Brücke's paper brought to the attention of Helmholtz, becomes more evident when we call to mind that the reflecting surface in Helmholtz's ophthalmoscope was not a silvered mirror, but a plate of plain glass set at a favorable angle.

And here, because a better opportunity will not present itself, we shall stop to describe an event of much interest in the history of ophthalmoscopy, though it had no bearing upon Helmholtz's invention and exerted absolutely no influence upon the subsequent evolution of the ophthalmoscope.

In 1847, four years before Helmholtz announced his invention, Mr. Charles Babbage, F. R. S., an English mathematician and inventor, by scraping off a little of the silvering from the back of a plain mirror, which he

set obliquely in a suitable tube, so that light falling upon it from an opening in the side of the tube should be reflected into the eye, contrived an ophthalmoscope which was much more like the instrument of to-day than was that of Helmholtz, and which unquestionably afforded a better illumination of the eye. But, unfortunately—as the writer of the article upon The Ophthalmoscope in *Chambers's Encyclopædia* remarks—the ophthalmic surgeon to whom he showed it did not recognize its importance, and he laid it aside without making it generally known. The “ophthalmic surgeon” alluded to was Mr. Wharton Jones, who, though he failed so egregiously to appreciate the value of Babbage's contrivance, deserves the credit, at least, of having put the facts with reference to it upon record, in a paper upon the ophthalmoscope published in October, 1854, in the *British and Foreign Medico-chirurgical Review*, and of having thus secured to Babbage the credit, undoubtedly due him, of being the inventor of the first ophthalmoscope.

Charles Babbage, or “Mr. Babbage,” as he was called in Wharton Jones's paper, and has been called by nearly every writer upon the ophthalmoscope since—except Perrin, who, in his article upon Ophthalmoscopie, in the *Dictionnaire encyclopédique des sciences médicales*, styles him B-a-b-b-a-y-e—seems to have been born under an unlucky star, and the want of success of his ophthalmoscopic venture was not his only, nor was it, perhaps, his greatest, bit of ill luck. Though a mathematician of decided ability, he failed to secure several professorial positions to which, in turn, he aspired; spent much of his own fortune and still more of the English government's money in prolonged, but only partially successful, endeavors to construct a calculating machine (which, in its unfinished state, may be seen to-day in the South Kensington Museum); was unsuccessful in an endeavor to enter Parliament; got himself into “hot water” by publishing an attack upon the management of the Royal Society; wrote a learned disquisition—which, fortunately, he never published—*On the Art of Opening Locks*, and then promptly proposed a plan for defeating his own methods, which was afterward patented; and, finally, in his declining years, gained great notoriety because of his “ferce hostility” to organ-grinders, in spite of whom—as his biographer in *Chambers's Encyclopædia* naively remarks—he lived till October 18, 1871, which, as he was born in 1791, was not wholly a bad record; though we have a lurking suspicion that the poor man really longed for an early demise, and in this regard, as had happened to him in so many other directions, went wide of the mark.

Professor Ames, of the physical department of the Johns Hopkins University, who, with the assistance of one of his students, Mr. James Barnes (4), has recently had occasion to review the life of Babbage, tells me that in not one of the biographical sketches of Charles Babbage, of which there are many in existence, is there the slightest reference to his having invented an ophthalmo-

scope. Such scant credit, indeed, is he given for this invention, that not a little research was necessary to enable me to assure myself that Wharton Jones's “Mr. Babbage” and the Charles Babbage of calculating-machine fame and the vindictive enemy of organ-grinders, were one and the same.

And now, having reached its consideration in chronological order, let us turn our attention to the ophthalmoscope of Helmholtz. And what shall we say of it? That it was the legitimate parent of all later ophthalmoscopes; that it was the first instrument with which the back-ground of the living eye was seen *distinctly*; that Helmholtz was absolutely the first to suggest the indirect method of ophthalmoscopy; and that it was he who directed the world's attention to the subject, are facts which are not open to dispute. But, having willingly accorded him this large measure of credit, I believe I do his memory no injustice in asserting *that what was essential in his ophthalmoscope was not wholly original, and that what was original was not only distinctly not essential, but was the outcome of a misconception—a fortunate misconception, as it turned out—upon his part.* Furthermore, it is a fact that within a few months of the announcement of his invention, the method of illuminating the eye which he suggested was, to a great extent, put aside for a simpler and more efficient method, which, indeed, was essentially that of the ill-starred “Mr. Babbage.”

It has already been intimated—and this, indeed, is but the commonly accepted view—that the reflecting sur-

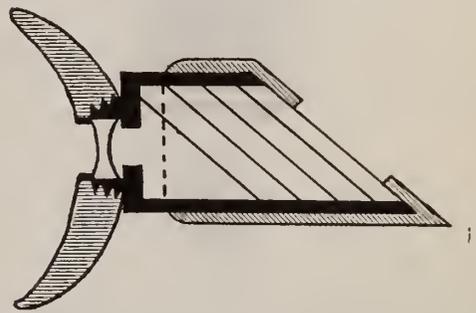

FIG. 1.—Helmholtz's ophthalmoscope, as represented in his original paper.

face of Helmholtz's ophthalmoscope, consisting at first of a single plate of plain, unsilvered glass, and later of several such plates in close apposition, was simply the practical application of von Erlach's observation, as recorded by Brücke. The other, and *original*, feature of his ophthalmoscope was the insertion of a concave lens between the glass plates and the eye of the observer. This lens Helmholtz was led to employ, because he reasoned that the eye under examination would focus for the image of the nearby flame reflected into it by the glass plates, and hence that the light returning from its fundus would leave the cornea in converging rays, which must needs be rendered parallel or divergent in order to afford clear vision to the observing eye.

Now, as a matter of fact, an eye under examination with the ophthalmoscope, and this is especially true of the direct method, shows but little inclination to employ its focussing power; so that, unless it is myopic, the light does not commonly emerge from it in converging rays. But, on the other hand, in the direct method of examination (the method chiefly relied upon by Helmholtz) the beginner in the use of the ophthalmoscope finds it extremely difficult to relax *his* accommodation, or, in other words, to focus for other than divergent rays of light, and he is, therefore, greatly helped in obtaining a clear view of the fundus of the eye by looking through a concave lens.

And so it came about that the concave lens of Helmholtz's instrument, although, as I have said, it was not an essential feature of a successful ophthalmoscope, and was employed by him to meet an unreal difficulty, was, nevertheless, of the greatest assistance to him and his earlier pupils, who were all, necessarily, neophytes in ophthalmoscopy, and who doubtless had the same trouble in controlling their accommodation that is experienced by the beginner of to-day.

How great *were* the difficulties at first experienced by Helmholtz he has himself set forth. In an address delivered many years later, after describing the first model of his ophthalmoscope as having been constructed of pasteboard and of eye lenses and cover glasses, such as are used in microscopic work, he says: "It was at first so difficult to use, that I doubt if I should have persevered

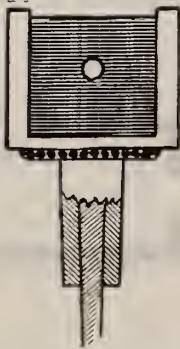

FIG. 2.—Early model of Epkens's ophthalmoscope (after Gould).

unless I had felt that it must succeed; but in eight days I had the great joy of being the first who saw before him a living human retina" (5).

The suggestion of the indirect method of ophthalmoscopy, or the employment of the inverted image (which is commonly attributed to Ruete), was made by Helmholtz in his first published account of his invention (6). He was not at this time favorably impressed by it, however, and did not commend it. Nevertheless, he did employ it later in what was known as his "simplest ophthalmoscope," which was nothing more than the method of illuminating the pupil by direct light, discovered by Cumming and Brücke, supplemented by the placing of a convex lens before the observed eye.

At the time of his invention of the ophthalmoscope, Helmholtz was professor of physiology at Königsberg, and he subsequently held the same position at Bonn and later at Heidelberg; and still later, in 1871, he became professor of physics in Berlin. He was especially interested in problems connected with the physiology of sight and of hearing, and, as an outcome of this, we have, besides his invention of the ophthalmoscope, his masterly treatise upon *Physiological Optics*, his great work on *Die Lehre von den Tonempfindungen*, his exposition of the mechanism of the ossicles of the ear, and his theory, commonly accepted, of the accommodation of the eye. He was born at Potsdam, on August 31, 1821, and, full of honors, died on September 8, 1894, having just passed his seventy-third birthday.

It was Epkens, an instrument maker of Amsterdam, who, within a few months of the appearance of Helmholtz's original publication, constructed an ophthalmoscope, to which allusion has already been made, in which a plane mirror, with the silvering removed from a small oval space in its centre, was substituted for the glass plates used by Helmholtz. The value of this modification was at once appreciated by Donders, who described the instrument, and commended it, in a paper published in the *Nederlandsch Lancet*. In the meantime, Rekoss, a "Mechaniker" of Königsberg, had improved upon the original model of Helmholtz's instrument by adding two revolving disks, each of which carried a series of lenses. The disks—which, in accordance with Helmholtz's idea, contained only *concave* lenses, varying in strength from 6" to 13" focal length (7)—were so arranged that by their revolution the several lenses, singly or in pairs, could be brought before the observer's eye. The Rekoss disks, as this contrivance was thereafter called, were presently adapted to Epkens's ophthalmoscope as well, and, indeed, in more or less modified form, they soon were, and are to-day, in very general use in the better kinds of ophthalmoscopes.

The next distinct advance in the evolution of the ophthalmoscope was made when Professor Ruete, of Göttingen, in 1852, for the better illumination of the eye, suggested the employment of a *concave* mirror in place of the plane mirror of Epkens. This was really the first ophthalmoscope that was adapted to the examination of the inverted image; and it is to Ruete that the credit is undoubtedly due of being the first to *appreciate the value* of this method; for, although Helmholtz had already described it, he did not, as has been mentioned, speak of it with favor, doubtless because the feeble illumination afforded by his ophthalmoscope was so ill-suited to it.

It is of interest to note, at this point, that, although the subsequent evolution of the ophthalmoscope was almost wholly the work of ophthalmologists, they took no part in the scientific observations which led to its invention, and had no hand in the invention itself or in the improvements made in it up to the time of Ruete. Whether the unwonted energy which, thereafter, they

displayed in this direction was due to a laudable desire to "even things up"—if I may be allowed the expression—I am unable to say; but certain it is that a veritable epidemic of ophthalmoscope-building now overran Europe. It was, perhaps, most virulent in Germany, but it spread from there to Austria, to Holland, to France, and to England, and a sporadic case (as to the genuineness of which there is, however, some doubt) (8) occurred even in far-off Greece. As the outcome of this, ophthalmoscopes of all sorts were constructed, many of them being cumbersome and complicated to a degree, and not a few of them resembling more nearly telescopes than the ophthalmoscopes of to-day. Unwieldy affairs, called fixed ophthalmoscopes, were much in vogue, and a deal of ingenuity was expended in the contrivance of binocular ophthalmoscopes, auto-ophthalmoscopes, and ophthalmoscopes for purposes of demonstration. Moreover, the almost forgotten observation of Méry, who, nearly a hundred and fifty years before, as he accidentally held a cat under water, saw the vessels of the retina and the color of the fundus of the eye, was called to mind, and, acting upon the hint which this observation afforded, suitably shaped cups, with one or more glass sides, intended to hold a small quantity of water in contact with the open eye and thus afford a view of its back-ground, were contrived—one by Czermak, another by Arlt, and still another by Coccia—and were modestly called orthoscopes; not, I take it, because their authors considered them the only right sort of "scopes," but because they afforded a direct view into the eye.

Of all these older ophthalmoscopes, as Gould remarks in his article upon Ophthalmoscopy in Norris and Oliver's *System of Diseases of the Eye*, only one—the small ophthalmoscope of Liebreich—survives to-day in the form in which it was first invented; the others have for us an interest which is simply historical. In the "lichtschwache Spiegel" of Jaeger's ophthalmoscope, which was in common use in Vienna when I was a student there, in 1871, and with which some of my earlier experience in studying the fundus of the eye was gained, the unsilvered mirror of Helmholtz's original instrument, probably, had its longest survival.

In the original description of his ophthalmoscope, Helmholtz not only predicted that, by its aid, nearly all that dissection had shown in the dead eye would be recognized in the living, but he pointed out, besides, that it afforded a means of determining, objectively, the optical condition, or refraction, of the eye. One of the first ophthalmologists to appreciate the significance of this suggestion and to employ the ophthalmoscope as an optometer, was, as Donders tells us (9), Edward Jaeger, of Vienna, who published a paper upon the subject in the early part of 1856 (10); and he was followed, somewhat later, by Stellweg, and, still later, by Mauthner. The earlier ophthalmoscopes, however, were ill-adapted to exact optometric work, not only because they were provided with too small a number of eye-lenses, but because these

lenses were placed at too great a distance from the mirror and hence from the observed eye.

The elimination of these shortcomings, the adaptation of the ophthalmoscope to accurate optometry, constitutes the next decided step in its evolution. And here, for the first time, American ophthalmologists come definitely to the fore. To the late Dr. Edward G. Loring, of New York, a larger measure of credit is unquestionably due than to any other one man for bringing the optometric or refraction ophthalmoscope to its present state of perfection, although he himself declared that it was Mauthner who deserved this honor (11).

Dr. Loring's description of his first ophthalmoscope was read before the American Ophthalmological Society in July, 1869, and was published in the *Transactions of the Society for that year*, as well as in the *American Journal of the Medical Sciences* for April, 1870. In its construction, his aim was to obtain a greater number of eye-lenses, to have these lenses large in proportion to the size of the central perforation in the mirror, and to place them as close as practicable to the posterior surface of the mirror. He accomplished what he had in view by setting the lenses, twenty-three in number, in three revolving, detachable metal disks, which were fitted close to the eye-hole of the mirror, and by having the mirror itself ground exceedingly thin and the metal backing beveled away around the central opening, so that as little impediment as possible should be offered to the rays of light returning from the observed eye. He was fortunate in his selection of an optician (Mr. H. W. Hunter, of New York) to carry out his views, and the result was that in delicacy and perfection of construction his ophthalmoscope—and this is equally true of his later models, also made by Hunter—far surpassed any of the instruments which had previously, and indeed any which have since, been manufactured in Europe.

In 1877, Dr. O. F. Wadsworth, of Boston, made, as Loring himself expresses it, "an ingenious and what promises to be a useful addition to my ophthalmoscope" (12). The addition consisted of a small circular revolving mirror, having a diameter of only fifteen millimetres, which was set at an angle of twenty degrees to the disk carrying the lenses. It was designed for the more accurate determination of errors of refraction by the upright image. This it accomplished through the tilting of the mirror, which enabled the observer to look directly, and not obliquely, through the eye-lenses, while the small size of the mirror permitted the lenses, notwithstanding the tilting, to be kept close to the central opening, an advantage which none of the older ophthalmoscopes with tilting mirrors possessed. This contrivance of Wadsworth's, however, was open to the serious objection that it necessitated the employment of two mirrors, since the small mirror did not give sufficient illumination for the indirect examination. Impressed with the importance of the principle involved in Wadsworth's suggestion, Loring at once set about contriving a mirror

which would accomplish the end Wadsworth had in view, and which would also be adapted to the indirect examination; and it was not long before he succeeded in doing this in a most admirable manner. By cutting away the lateral portions of the circular mirror previously employed, he produced the rectangular, swinging mirror which is now so generally used, and which is hardly likely ever to be put aside, since it fulfills its purpose so perfectly.

In the following year (1878) Loring, who previously had done away with the three detachable disks of his first instrument and substituted a single disk carrying twenty-four lenses set in two concentric circles, and had also adopted the metric system for numbering the lenses, put what may be called the finishing touch to his ophthalmoscope, and made it the admirable instrument which it is to-day, by rearranging the lenses in the disk and adding a revolving quadrant, carrying four additional lenses (13). By this ingenious arrangement, the lenses in the quadrant being combined, when required, with those in the disk, he obtained a series of sixty-five glasses, varying in strength from a .50 dioptré to + 23. and - 24. dioptrés, a series sufficiently complete for all practical purposes.

Dr. Edward G. Loring, who was born in Boston in 1837, and for a while, in 1865, practised his profession in Baltimore, whence he moved to New York, was a man of marked ability, and it was said of him, shortly after his death, and justly, I believe, that by his writings upon ophthalmological subjects and by his perfection of the ophthalmoscope, he had done more than any other one man to place American ophthalmology abreast with that of the world (14). Besides being a frequent contributor to current medical literature, he was the author of a *Text-book on Ophthalmoscopy*, upon the revision of the last volume of which he was engaged at the time of his death, which occurred very suddenly, probably as the result of an embolism of the coronary artery, on April 23, 1888. His death, when he had but reached his fifty-second year, and was, mentally, as vigorous as he had ever been, was a distinct loss to modern ophthalmology.

Among others who have turned their hand to the construction of ophthalmoscopes especially adapted to optometry, may be mentioned de Wecker, Knapp, Strawbridge, Noyes, Couper, Morton, Hawes, Randall, and Jackson. The ophthalmoscope devised by Mr. Morton, of Moorfields Hospital, London, is, perhaps, the strongest rival of Loring's instrument; but, in my judgment, is not its equal, though it has undoubted merits. The lenses of Morton's ophthalmoscope, of which there are twenty-nine, are enclosed in an endless groove, and are propelled by a driving wheel. In addition to these, there are four lenses set in a revolving disk, which may be combined with those in the groove. It is provided with three tilting mirrors of the type suggested by Wadsworth. These are set in an arrangement similar to the nose-piece of a microscope, which revolves upon a central

pivot, bringing the mirror desired into the proper position for use. One of the mirrors is plane and is intended for retinoscopy; another, which is concave, with a focal length of ten inches, is for the inverted image, and the third, a small concave mirror of three inches focus, is meant for the direct examination. The first two named are set, back to back, in one mounting and are reversible. It is not so wieldy an instrument as Loring's, being considerably heavier; and, as commonly made, the distance between the lenses and the sight-hole of the mirror is inconveniently great.

And now, fearing that I have already exhausted your patience with wearisome details concerning inverted and upright images, tilting mirrors, and revolving disks—which, however, could not very well be omitted—I shall hurry to a conclusion, making only a few brief observations upon what the ophthalmoscope has done for medicine, the second part of my theme.

As has happened in like circumstances before, and as probably will happen to the end of time, when the ophthalmoscope was first brought to the world's attention by Helmholtz, much skepticism was shown as to its real value, and not a little reluctance displayed on the part of ophthalmologists, especially those of the older school, in adopting it as an essential part of their armamentarium. Perhaps I cannot better illustrate this point than by quoting a few paragraphs from a Short Account of the Ophthalmoscope, by Addinel Hewson, in the American edition of *Mackenzie on the Eye*, published, under his editorship, in Philadelphia in 1855. After giving a description of Helmholtz's ophthalmoscope, he expresses himself as follows: "A great deal more, however, has been expected of, and claimed for, the instrument than it is capable of accomplishing in the present state of its construction.

"In the first place, the great concentration of light which it produces in the eye [*sic*] renders its employment highly injurious, even for a few minutes of time in the incipient stages of disease. In cases where it can be endured, its employment for any length of time sufficient to detect all the changes which have taken place produces an excited and unnatural condition of the structures which are the subject of investigation, and might readily lead the observer astray in his diagnosis."

However, as is shown by the following quotation from Jabez Hogg's *Ophthalmoscopic Surgery*, published in London, in 1863, in spite of skepticism and pessimistic prognostications, the new instrument grew in favor rapidly, and soon came to be appreciated at its true worth. "It is indeed curious," says Mr. Hogg, "to mark how men of established reputation, who, as a rule, are averse to novelty, and unfriendly to innovation, have, one after the other, . . . surrendered their alleged objections and become the strongest advocates for the use of the ophthalmoscope, when its revelations were found to be obviously sound to admit of being disputed. . . ."

Among the first to appreciate the true import c

Helmholtz's invention, and to acquire facility in its use, were von Graefe—to whom Helmholtz sent one of his earlier instruments—Liebreich, who was an assistant of Helmholtz's at the time the ophthalmoscope was invented; Donders and Jaeger, as has already been mentioned; Desmarres and Sichel, in France, and Bowman and Hulke, in England. Dr. E. Williams, of Cincinnati, who, in an article published in the *Medical Times and Gazette* (London), in 1854 (15), spoke of the ophthalmoscope in terms of high commendation, was the first, according to St. John Roosa, to introduce the new instrument to the knowledge of the medical profession in this country (16). He also states that he was the first to bring it to the attention of the profession in England, but in this he is evidently mistaken (17).

The names which I have enumerated one is not surprised to find connected with the early history of ophthalmology; but there are others mentioned in this connection of which this cannot be said. For example, one hardly expects to be told, as Clifford Allbutt tells us in the introduction to his work on *The Ophthalmoscope*, that "Mr. Spencer Wells was among the first in England [in an article published in the *Medical Times* for September 10, 1853] to insist upon the great value of the ophthalmoscope in diseases of the eye." And, coming nearer home, we find, in a *Report of the Committee upon Surgery*, presented to this Faculty but a few months later, on June 7, 1854, by Dr. Christopher Johnston, a comprehensive and interesting account of the ophthalmoscope of Helmholtz and of several of the other early instruments. Two ophthalmoscopic drawings, by Dr. Johnston, accompanied the report, which goes on to describe how "all observers are unanimous in their expressions of delight as regards the spectacle afforded by the inner eye." And, with still more interest, we read further on that "one of your committee [Dr. Johnston] also has experimented with Helmholtz's speculum (18), in Berlin with von Graefe, in Paris with Desmarres, and in Baltimore with Professor George W. Miltenberger" (19). This description of the ophthalmoscope by Dr. Johnston was certainly one of the earliest published in this country, and it seems highly probable that the very first colored drawings of the background of the eye published in America were those which he prepared, and which, as I have said, appeared in our own *Transactions*, in 1854. The report also makes it evident that our honored confrère, Dr. Miltenberger (20), must have turned his attention to the ophthalmoscope at about the same time that Mr. Spencer Wells was pointing out its merits to the medical profession of England.

To the question, What has the ophthalmoscope done for ophthalmology? perhaps a more comprehensive answer cannot be given than to say *it has done all that Helmholtz promised it would do*. His prediction was, that it would show alterations in the retina just as the unaided eye sees them in the cornea and iris; that it would enable us to detect congestion of the retinal ves-

sels and inflammatory exudations upon or in the retina or between it and the chorioid; that it would permit us to recognize more easily and certainly the presence and degree of opacities of the crystalline lens; that by its aid we should be able to detect the existence and measure the amount of short-sightedness and far-sightedness; and that, in short, nearly all that dissection had shown in the dead eye it would enable us to recognize in the living one. A more striking example of prevision than is afforded by these prophetic assertions of Helmholtz it would be difficult to find.

To comprehend fully the veritable revolution which the invention of the ophthalmoscope brought about in ophthalmology, one needs but to glance over the "table of contents" of any of the standard works upon diseases of the eye published prior to this period, and more especially to note, under the heading "amaurosis," the varieties and sub-varieties of this affection which are enumerated, the causes assigned for it, and the remedial measures suggested to combat it. The aphorism of Walther, "Amaurosis sei jener Zustand wo der Kranke nichts sieht, und auch der Arzt nichts," is too apposite not to be cited in this connection, though it has been quoted so often as to have become a veritable "Joe Miller."

Ophthalmology, deprived to-day of the ophthalmoscope, might be likened, perhaps, to a ship without a rudder; but, if a wind could *be* so ill as to carry away, at once, compass and sextant and rudder as well, such a ship, so bereft, it seems to me, would afford a still more apt comparison.

But ophthalmology is not the only department of medicine that is beholden to the ophthalmoscope. The specialist in diseases of the eye had hardly learned to appreciate its value, before his brethren interested in affections of the brain and nervous system began to realize how great a boon it was to them as well. Von Graefe and Sichel were among the first to recognize and point out the close relationship existing between optic neuritis and intracranial diseases. Hughlings Jackson, in London, and Clifford Allbutt, in Leeds, profiting by their suggestions, were the first to approach the subject from the standpoint of the neurologist, and they may well be called the fathers of medical ophthalmology. And right well have their labors been supplemented by another English worker in this same field, Dr. W. R. Gowers, whose *Manual of Medical Ophthalmology*, like Clifford Allbutt's treatise *On the Use of the Ophthalmoscope in Diseases of the Nervous System and of the Kidneys*, is too well known to need more than passing mention.

A long list of maladies, other than those of the brain and nervous system, in which intra-ocular changes, more or less characteristic and hence of diagnostic value, are revealed by the ophthalmoscope, such as Bright's disease, diabetes, pernicious anæmia, leucocythæmia, angioid sclerosis, etc., might be dwelt upon; but I have not the

temerity to tax your patience further, and, besides, unless the principle of reciprocity is to be wholly ignored, it is incumbent upon me to show you, at least, a modicum of the consideration which you have so generously accorded me, and for which I—thank you.

AN INTRODUCTION TO THE PSYCHOLOGICAL STUDY OF BACKWARD CHILDREN.

BY WILLIAM B. NOYES, M. D.,

NEW YORK,

ATTENDING NEUROLOGIST, DEMILT DISPENSARY.

It is often difficult for one who may be well grounded in the principles of his own science or profession to realize that, in order to understand some important and difficult questions placed strictly within the limits of his own subject by the classification in common use, he must transfer his study to fields which at first sight seem to be entirely outside of his own proper sphere of work. There is no better illustration of this than in the subject before us for study this evening. To gain a proper appreciation of the study of mentally defective and backward children, one must look at it from the standpoint of the psychologist and teacher as well as of the physician. The study of the normal as well as of the abnormal child belongs equally to all three professions. "The study of physiology," says Bain, in beginning his work on *Education as a Science*, "is the theoretical guide in finding out how to rear living beings to the full maturity of their physical powers. The art of education assumes a *certain average physical health* and does not inquire into the means of keeping up or increasing that average." Yet every family physician realizes how constantly the children under his care vary in their physical condition, and no one doubts that the science of education must adapt itself to their varying needs. When it comes to the abnormal children who, from faulty physical or mental development, are more or less below the average, while we are well aware that in the past the public systems of education have taken little cognizance of these defectives, and even the feeble-minded children of the wealthy have often had less skilled educators than their normal brothers and sisters, it would seem to be one of the most important questions connected with education.

and one that deserves attention from the public and careful study on the part of the medical profession.

For this reason, all discussion of the work of scientific education as applied to the class of defective and backward children is valuable.

The medical profession has certainly realized the importance of psychology of late. The development of such annoying fads as "Christian Science" and allied forms of "mental healing" which are attaining certain definite results in individual cases, not always obtained by ordinary methods of therapeutics, must convince the most sceptical of the value of suggestion, for suggestion is one practical application of psychology and pseudopsychology, no matter how crude and vulgar its methods may be. Suggestion has usually been at the bottom of the cures attained by the various quack medicines. Suggestion has been doing its work in influencing the minds of men from the earliest days of witchcraft and miracles up to the present. Mesmerism and "animal magnetism" were long in losing their cloak of mystery, and in later years the subject of hypnotism has only recently been placed in its correct place as dependent upon and associated with suggestion.

But suggestion has far outgrown its original limits as a part of quackery and as a part of hypnotism and ordinary therapeutics. In a recent work by Binet, representing the position of the modern French school, a study of the relation of suggestion to education is made, and all children are classified as follows with reference to their suggestibility:

1. Children who are more or less of an automatic type, who obey passively the will of their teachers. They are models of discipline and represent the average "good" school child.

2. Sensitive children, from whom obedience is obtained by an appeal to their emotional nature, who respond to suggestion most readily when it is based on an appeal to their affections.

3. Those children whose minds are active and bright, who have a sharply defined personality, upon whom it is difficult to act definitely by suggestion unless by calling up the spirit of overcoming an obstacle. They do best what they are told they cannot do.

4. The class who are obstinate and rebellious to all suggestion or incapable of following any suggestion whatever. This class includes all undisciplined, insubordinate children and a large class of neurotic and degenerate types. In this class are the children who are morally perverse and eventually become interesting from the standpoint of criminology. It includes all backward and feeble-minded children and the mentally defective in various ways.

Recognizing the truth of a rough classification of children with reference to their suggestibility, for suggestibility must be the basis of methods used in education, we realize how grave is the problem of children who must be included in the last class. Before any progress

can be made in studying the care of this class of defectives we need something more satisfactory as a classification of its various types, which all agree in being unable to respond to suggestion as normal children do, and which even at the best give so much trouble to their teachers by their defects or perversity that they must be placed outside of the class of children who are properly considered as candidates for the ordinary schools.

There are included with them neurotic children, who, at first sight, might seem to belong to this class from their actions and mental condition, who are really suffering from symptoms of hysteria or epilepsy or chorea. Temporarily they would seem to belong to this class, yet they are capable of such improvement, and not infrequently are mentally so much brighter than other children, if their physical health is improved, that they may better be classed with the sick rather than the mentally defective children. A fifth class might be made for this type of cases, based on their suggestibility, including all children whose suggestibility is excessive and abnormally great, as is usually the case in the hysterical and allied conditions.

It is remarkable how little attention the books on mental diseases give to any of the psychological conditions lying between what is normal and such hopeless conditions as imbecility and idiocy. There are many such intermediate conditions of abnormal mental development which are regarded by relatives, physicians, and teachers in various ways. Some of these cases at first sight are wrongly taken to be really idiocy or imbecility. Others vary from the normal only by defect in some single faculty of the mind. Every school contains pupils who are regarded as generally backward and stupid, when their entire trouble lies in one single mental faculty.

In every one of these cases, if we would rightly interpret the individual mental conditions, we must cease considering the words "backward or mentally defective child" as a diagnosis and make as careful an examination of each mental faculty as we would make of each separate organ of the body if we were expecting to make a clinical diagnosis. Such an examination may yield the key to the future mental development of the child in an entirely unexpected direction. Two other general terms to be used with utmost care are degeneration and heredity. The study of these two subjects during the last years has certainly cast some light on the subject of defective children, and yet at the present moment no word is more often misapplied than, or applied in so many different ways as, the word "degenerate," and no laws are blinder than the so-called laws of "heredity." Some of the defective children present a history of definite physical disease or definite traumatism before, during, or after birth. Some are born into the world with their tissues poisoned or weakened from disease inherited from their parents. Some give no clue to any definite organic disease, and the pathological findings at autopsy

show in some cases definite lesions of the brain, in other cases nothing tangible. But the mental condition in these cases, however varied may be their ætiology or pathology, is often identical. For this reason it is better to make a detailed study of the individual mind in question and to ignore the obvious pathological conditions and the heredity for the time being.

To illustrate this I will invite your attention to a case which at first sight would seem to be an ordinary, typical case of a feeble-minded child, in order to illustrate the difference between a medical and a psychological diagnosis:

G., a boy aged sixteen; parents nervous, but otherwise unusually healthy people, who had suffered from the strain of intense business worry during the year before his birth. Birth instrumental, with definite asphyxia on the part of the baby, said to have lasted an hour, followed by convulsions, which recurred at frequent intervals for a week, but not afterward. Dentition, walking, and talking much delayed. He was sent to school when eight years old, but made slow and unsatisfactory progress. His disposition was obstinate and selfish, but affectionate at times to his parents, though he was generally eager to annoy them in little ways. He was a bad stammerer, using violent gestures when excited.

The physical examination was as follows: Head rather microcephalic. Palate, high-arched or Gothic. No paralysis or contracture. Physique that of a tall, splendidly developed boy, with no definite stigmata of degeneration except the arched palate. His general health was not good; he was constantly complaining of symptoms referable to constipation and torpid liver. His mind was changeable, easily excited, and obstinate. He lacked application. He would not associate with any other boys but his brother, or play in any sport excepting pool and billiards. His father stated that he was profane in language and fond of low company. My diagnosis was asphyxia at birth, with probable resulting minute meningeal hæmorrhages, mental weakness, and instability of the type seen in the majority of such cases, following asphyxia or convulsions in early infancy.

As a psychological study the case presents a different appearance. The only line of treatment beyond methods directed toward the nervous symptoms was some form of definite instruction partly for the stammering and partly for the general ignorance. I found that he was able to read, but absolutely unwilling to read anything except sensational newspapers. He could write, but would not write anything but his name. He stammered as badly with his pen as with his voice. It seemed absolutely impossible to interest him in any subject that would ordinarily appeal to boys, with the single exception of prize-fighting and sporting matters. He took some interest in a typewriting machine with which I tried to train him, with the idea not only of getting him to do something and improve his spelling, but chiefly to demonstrate how much attention he could develop and maintain. I discovered that in spontaneous attention, meaning thereby the natural attention to ordinary subjects of casual conversation, he was not absolutely deficient, but that voluntary attention was a faculty in which he was so deficient that I feel justified in calling the basis of his trouble a definite disease of the faculty of voluntary attention.

He was seemingly unable by any effort of his own to concentrate and to hold his attention. But in spelling he would often balk at words of one syllable, while spelling long words correctly. When at one time, hoping to find a subject that would interest him, I asked him to write an account of the Corbett-Fitzsimmons fight, which had just occurred, to my surprise he wrote a full page, giving a complete biography of each pugilist, the number of battles each had fought, and the number of rounds in each (quite a feat of memory for any one).

I concluded that the defect or disease of the will was more responsible for his condition even than the lack of attention. In many respects he was morally obtuse, and the condition might have been called in ordinary language simple obstinacy and moral ugliness of disposition. But a year's continuous study of the case made the diagnosis of a disease of the faculty of will seem definite. He was as unable to compel or direct his attention or control his mental activity as he was to control his stammering. He had partial control of each, not more. Both conditions improved remarkably when the general health was improved by drugs, and under these circumstances a genuine all-around improvement was evident to every one, but a fit of constipation seemed often to undo it all for the time being.

The older works on psychology divided the mind into sharply defined sub-divisions and considered each one of the different mental faculties as if it could act by itself, independently of all the others. This system, though certainly convenient, is no longer considered good psychology, for each mental faculty is too closely dependent on each and every other mental faculty to permit such accurate vivisection or physiological isolation. But in conditions of disease or in the distinctly abnormal mind the disassociation which has already taken place, even in the milder cases, makes the method of sharply differentiating mental faculties not only permissible but necessary.

In our study of mentally defective children we may distinguish:

1. Those in whom the *faculty of perception* is deficient, and this includes all those who have been born defective in their special senses, the blind, the deaf, and the dumb, who can only develop mentally by some vicarious education of other faculties. In the extreme types we have the so-called idiots by deprivation, who are idiots simply because they lack certain special senses.

2. Those children who, in spite of possessing all special senses and power of perception, lack the *power of attention*, without which the most painstaking instruction or frequently repeated suggestion is without result. In its worst degree, where attention is not to be aroused by any stimulus from without or within the mind, we have the idiot in his various types, showing, as has been so clearly noted by the recent French writers, in what a defective condition the human mind is bound to remain for life if the single faculty of attention is lacking.

Those children who fail absolutely in attention do not seem to be able to advance in any other mental fac-

ulty. Those who can by some form of stimulus have a moderate degree of attention aroused will respond to instruction and make definite progress. It would seem as if the possession of a very little power of attention would give a chance for the conscientious teacher to increase it to an indefinite degree. It is on this principle that most of the practical methods for training defectives are based. But, unfortunately, when we add to the fact that the method of using the mind in an individual child is faulty the fact that the innate power of using the mind and directing its attention is feeble, we shall understand the difficulty of the problem. It is, unfortunately, true in a very sad and literal sense that many of these defective children are "born tired," and this fatigue of the brain cells, in the same way as the fatigue produced by every kind of motor exertion, is so soon developed by any attempt to exercise it that it is hard to get any prolonged work of any kind done. Even the brighter defective children tire quickly in physical and mental activity. Others seem to lack the strength to begin. Attention is in its nature a motor function. It is associated with a definite muscular activity, active for certain muscles, inhibitory for others. It is rather the rule where failure in attention is serious to find other defects of motor functions, such as muscular tics, stammering, choreiform or epileptoid movements, an old paralysis or contracture, or athetoid movements of one or more extremity.

In those feeble-minded children less seriously affected various conditions will be seen where the attention is moderately deficient, spasmodic, fluctuating, or only occasionally in evidence. In fact, there are few normal children who do not show some evidences of inattention, but in their case the simplest devices of the teacher's art secure their attention again. In the pathological cases, to gain or hold the attention is a very different matter.

The third class is one which is characterized, not by defect of special senses or the power of attention, but by *defect or disease of the will*. Of this, the case reported is in some respects an example.

3. Diseases of the will may be classified as follows:

(a) Impairment of the will by defect of impulse, varying from sluggishness or irresolution, not uncommon among children, to extreme types of what is called abulia, or "idiocy of the will," which is a complete lack of will power and decidedly rarer. Persons of this sort suffer from a relative insensibility affecting the emotional life and often develop a definite psychic paralysis which may appear like a definite organic paralysis of the body or a part of the body. (b) The will may be impaired through a morbid fear or a fixed idea; among children this is usually regarded by parents as a silly notion of an imaginative child and not anything serious, and in reality it seldom persists long in any one definite form. In adult life these phobias, or minor fixed ideas, are common enough. They affect the will directly in proportion to their persistence and intensity. In child-

hood definite fixed ideas or lasting imperative conceptions are sometimes found. As a basis for the failure of volition exhibited in mentally defective children the possibility of hidden, fixed ideas must not be forgotten. (c) The will may be impaired through some excessive impulse which may be instantaneous in its onset or something more gradual. The passionate outbursts of children, especially common in those of an epileptic tendency, illustrate this. Even homicide or suicide may result, sexual misdeeds or other criminal deeds. (d) There may be impairment of the will due to a *lack of power of attention*. This may be congenital, as in the case reported, or acquired, as seen in various neuroses and psychoses. Chorea is an example of the acquired form of loss of voluntary attention where often, even before the motor restlessness has developed, a failure in attention and of will power becomes evident in a child previously studious. Nervous conditions produced by overwork sometimes show this symptom, and frequently the temporary mental changes which may develop during the period of puberty. (e) The will may be limited or practically destroyed by being controlled by the *caprices of hysteria*. This loss of will power is probably one of the most constant of all the symptoms of hysteria, whether in an adult or in a child. (f) The will may be in abeyance in conditions allied to *hypnotism* which are seen in childhood, chiefly in connection with morbid religious revivals and similar mental excitements. The state of hypnotism itself, if developed in a child for experimental purposes, is an example of temporary abeyance of will power.

4. While attention and will are in a way associated with motor functions, the *higher, or cognitive, powers of the mind* seem more related to the sensory functions. A child may be normal in perception, attention, and will, and yet decidedly deficient in reasoning faculties. The simplest use of language or thought calls for the ability of the mind to analyze or put together various facts represented by the words of the sentence spoken, heard, or thought. This faculty has made tremendous strides in developing in a normal child by its third or fourth year. But an older child who for any cause has not developed it, and who does not reason or make any advance in what is commonly called judgment or common sense, is best characterized as a *fool* rather than an idiot or imbecile. Such a child may not be considered at first a feeble-minded child, but when he grows older and shows absolute lack of judgment in every way for which his growing responsibilities give an opportunity, it is only too evident that from the beginning he was a defective and more or less of a fool.

Those educators connected with the schools for feeble-minded will agree to the statement that many a semi-idiotic or imbecile child that has received the best special education will remain in the end in this class of foolish children, lacking judgment and common sense. But this is infinitely higher than where he started.

5. There are cases where the child has normal senses, power of attention, will power, and reason, but fails in *memory*, or the power to recall what may have been acquired in the near or remote past. These amnesias occur in a progressive form after meningitis and excessive masturbation and acutely after traumatism, epilepsy, severe mental shock, and various febrile conditions and intoxications. They are marked in imbecility developing in the later years of childhood and in the acute psychoses of the period of puberty.

6. The last and most important class is that of the *morally defective*. To develop attention, will, and reason, a moral basis is necessary. Mere curiosity will only insure a low degree of attention and progress. A certain amount of ambition and self-respect must be developed to insure any real mental development. Under the class of moral imbeciles are types of children who are inherently bad and practically incurable. The study of this type is really the study of criminology, at least of juvenile criminals. Bad as the prognosis is, for degeneracy seems to have its fullest development in the genuine moral imbecile, the necessity of a correct psychological diagnosis is even greater here than in any other division of this classification, of which moral imbecility is the last stage. There are many minor degrees of moral deficiency.

In closing, it will be necessary to make one more class in answer to the criticism that will certainly be made of my classification, that such sharply defined types with pronounced defect of only one mental faculty do not, as a rule, occur; and that most feeble-minded children are affected, to a greater or less degree, in all their mental faculties. This is true of a large number. There remains a class showing *mental stupidity*, which is the simplest term for uniform mental deficiency affecting the different mental faculties at the same time. Such children, though possessing special senses, do not really perceive. Attention, volition, reason, and moral faculties are not and cannot be developed to any great extent. This condition in its milder degree is stupidity; in its more pronounced degree dementia. It stands apart from the special conditions which have been described in detail.

28 WEST SIXTY-FIRST STREET.

INGUINAL BUBO AS A COMPLICATION OF MALARIAL FEVER.

BY A. C. SMITH, M. D.,

PASSED ASSISTANT SURGEON, UNITED STATES MARINE-HOSPITAL SERVICE.

My attention has been attracted a number of times within the past dozen years to a group of symptoms which I have never seen described in any text-book on medicine or in current medical literature, and which may

be of special interest and importance to report at the present time. The group consists of inguinal bubo associated with malarial fever, the bubo being most commonly non-suppurating and the fever of the æstivo-autumnal type, though not invariably so. The bubo, in the cases which I am about to report, occurred without suspicion of venereal infection and was clearly secondary to the fever and dependent upon it.

The cases are presented solely as a clinical study. I regret that no blood examinations can be given with them. All were observed before the day of universal blood examinations in malarial fevers had arrived. The course of the fever and the mode of recovery in each are sufficiently distinctive, however, to place the diagnosis beyond probable dispute.

CASE I.—No clinical notes at hand. Supplied from memory. The patient, a colored man, was in one of the wards of the Marine Hospital at Stapleton, Staten Island, in the early part of the year 1889, suffering with necrosis of the toes as a result of frostbite. No septicæmia or confined pus. Temperature running normal. One day, about noon, he was seized with a chill, ushering in a sharp rise of temperature. At the same time a considerable swelling appeared in one groin, reaching its maximum quickly and causing the patient much pain. There was no trace of inflammation of the lymphatics or veins leading up the leg from the toes, or of erysipelas or other local infection. The fever went off with a profuse sweat before the following morning. An abundance of quinine was given and there was no return of the attack. As the fever subsided the bubo disappeared and left no trace.

CASE II.—Observed at Galveston, Tex. A native of Denmark, aged thirty-three years. Admitted to hospital August 12, 1891. The patient has a large and very ripe suppurating bubo in the right groin. The bubo appeared about four weeks ago. He does not know of any recent venereal infection which he has had and there is no evidence of any venereal sore. Says he has had no sexual contact within three months. Has not been feeling well for a couple of weeks. At first the bad feelings seemed to come every other day. Appetite poor and bowels inactive. Has taken no medicine. Temperature, 38° C. on admission. Treatment, a calomel cathartic.

August 13th.—The bubo was opened freely and flaxseed poultices, made up with bichloride solution, applied. ℞ Liq. potass. arsenitis, three drops t. i. d.

August 14th.—Dose of Fowler's solution increased to four drops. Fever absent this morning.

August 15th.—Temperature up again. Calomel repeated. Fowler's solution stopped and quinine bisulphate ordered in ten-grain doses, with two and one half grains of capsicum, at 6 and 7 A. M. to-morrow.

August 16th.—Three doses of the quinine bisulphate, with capsicum, ordered for to-morrow morning and thereafter till stopped. Iodoform dressing applied to sinus in groin.

August 19th.—Slight variations of temperature continue. Sinus in groin closing slowly.

August 21st.—A calomel cathartic again.

August 23d.—Quinine bisulphate continued without the capsicum.

August 25th.—Four ten-grain doses of quinine bisulphate given—at 6, 7, 8, and 9 A. M.—after which the

drug was stopped for the present. A calomel cathartic given.

August 28th.—Quinine resumed.

September 4th.—Quinine stopped.

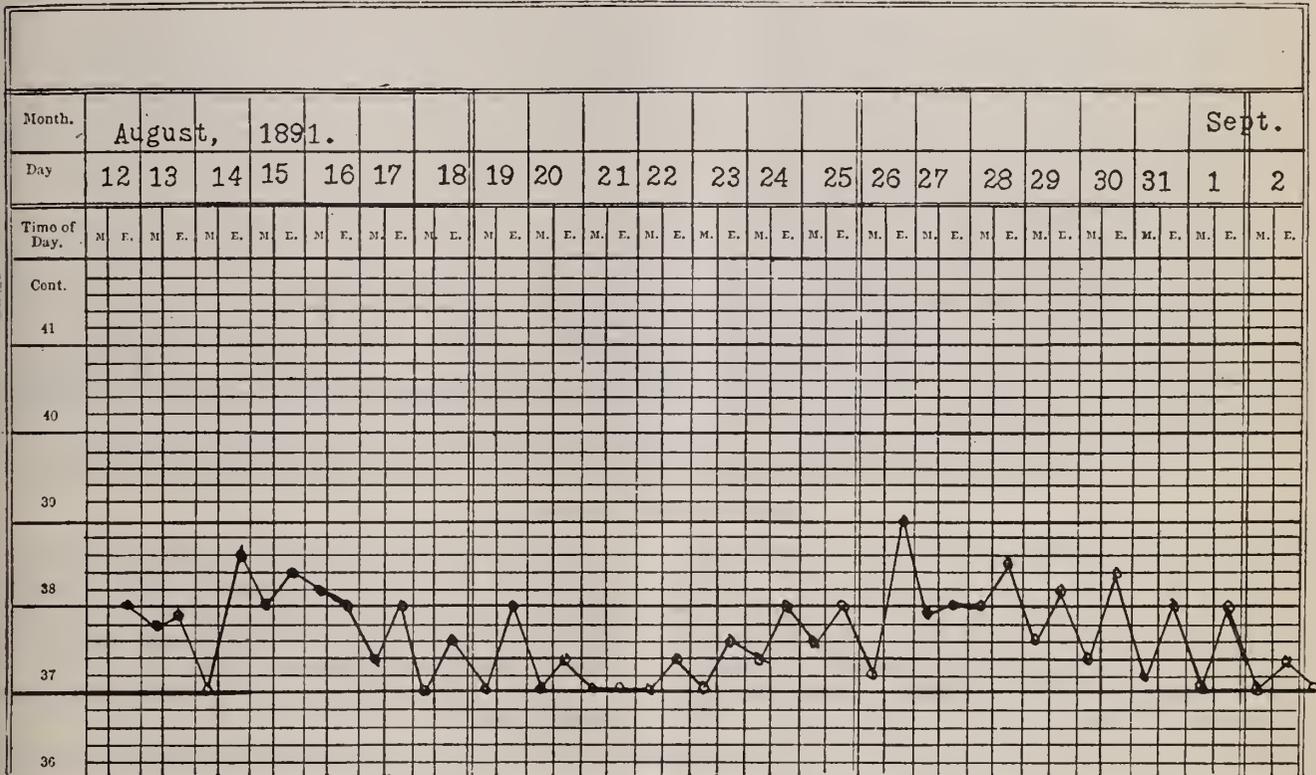

September 8th.—℞ Liq. potass. arsenitis, three drops t. i. d., increasing the dose by one drop each day up to eight drops.

September 10th.—Fever absent. Wound in groin closing rapidly.

September 2d.—Temperature almost down to normal. Patient had slight diarrhoea.

℞ Calomel. 3 grains;
 Bismuth subnitrate. 15 "
 Ipecacuanha. 3 "
 Dover's powder. 7½ "

M. Divide into three powders. Sig.—One at 10 A. M. and at 1 P. M. and 5 P. M. to-day.

Temperature Chart for Case II.

September 14th.—Fowler's solution stopped at morning visit. Later in the day the patient had a chill, with moderate fever, and an acid solution of cinchonidine sulphate was ordered.

September 23d.—All medicine stopped.

September 26th.—Fever has been absent since September 15th. Groin healed. Discharged, recovered.

CASE III.—Observed at Galveston. A native of Nova Scotia, aged twenty years. Admitted to hospital August 27, 1891. The patient applied for treatment, complaining of bubo in the right groin. The glands were found to be indurated, and slight induration of the glands in the left groin also existed. As there was no sign of venereal infection, I inquired for symptoms of fever and found that the patient had not been feeling well for a week, and had apparently had an exacerbation of fever the day previous to admission. Temperature on admission, 38.6° C. Tongue coated white. Bowels had been acted upon with a cathartic. Temperature rose to 40° C. at evening. ℞ Quinine sulphate, in ten-grain doses, at 6, 7, and 8 A. M. daily, beginning to-morrow.

August 28th.—Stramonium ointment applied to both groins.

September 1st.—Quinine increased to forty grains daily, given in morning doses as before.

September 3d.—Diarrhoea not yet checked; continue treatment.

September 5th.—Diarrhoea has ceased. Temperature normal this morning for the first time since admission.

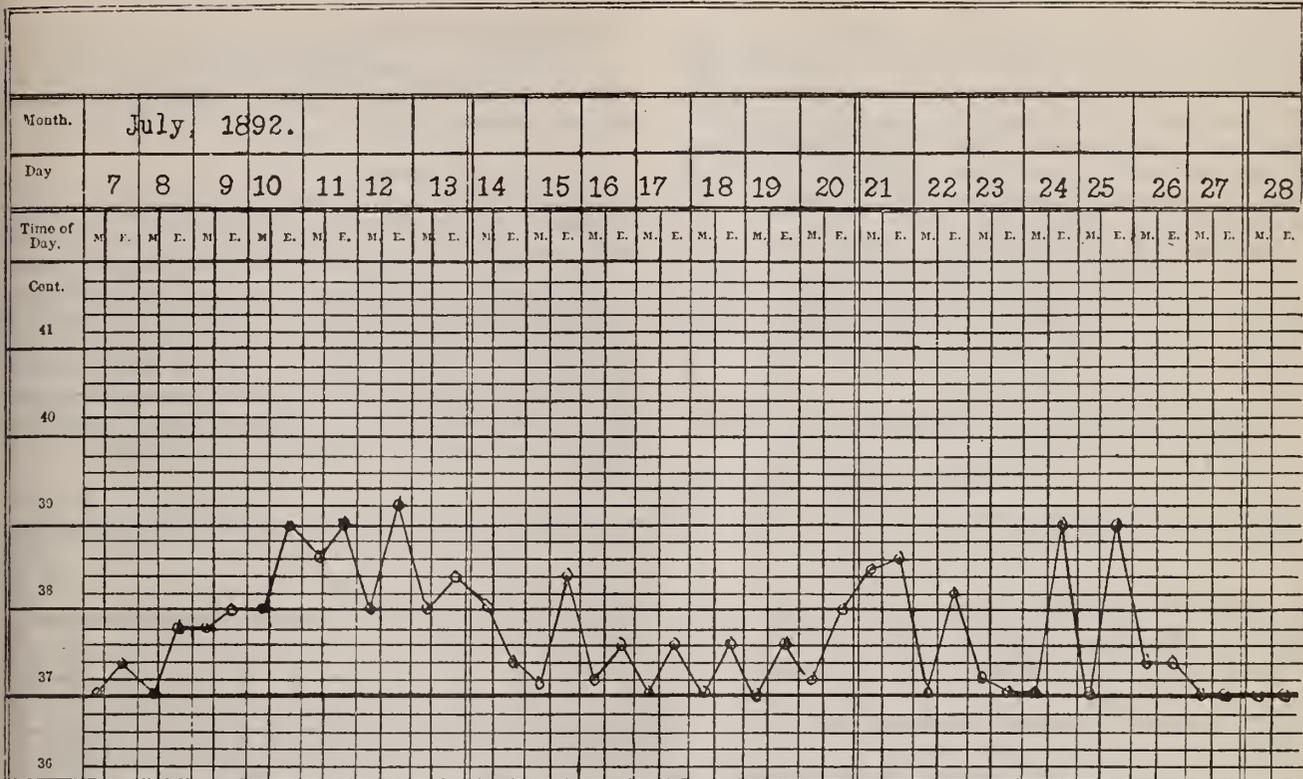

September 7th.—Quinine stopped.

September 8th.—Slight variations of temperature continue. ℞ Liq. potass. arsenitis, three drops t. i. d., increasing the dose by one drop each day up to eight drops.

September 14th.—The buboes have almost entirely disappeared. The patient looks puffy about the eyes from too much arsenic. Fowler's solution stopped and an iron tonic given.

September 20th.—Discharged, recovered.

CASE IV.—Observed at Galveston. A native of Norway, aged twenty-eight years. Admitted to hospital February 9, 1892. Patient has an inflamed bubo in the right groin and a temperature of 38.4° C. The bubo made its first appearance nearly two weeks ago. He has had a few chills at irregular intervals, but has been ill every day without intermission. Lately arrived from Morgan City, La. Tongue red and flabby and lightly coated. Bowels rather loose. A moderate calomel cathartic was given and quinine sulphate ordered in ten-

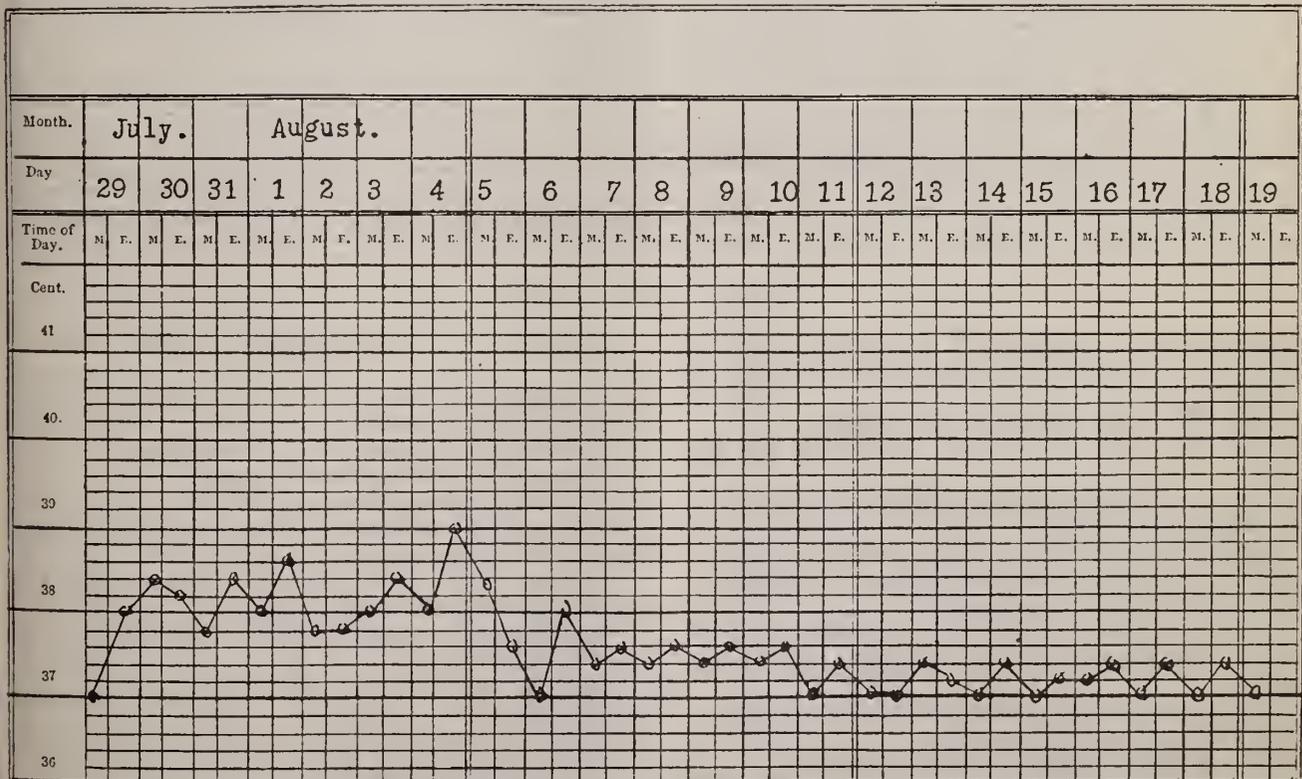

Temperature Chart for Case V.

February 20th.—The patient has had no fever since the 12th and is getting strength rapidly. The bubo is decreasing in size. Discharged from hospital and continued as an out-patient, and treated with the cod-liver oil mixture above noted and a tonic of iron, quinine, strychnine, and arsenic.
 The patient was under observation until March 15th,

at which time the bubo had disappeared, only slight induration of the lymphatics in the affected groin being perceptible to the touch.

CASE V.—Observed at Galveston. A native of Norway, aged thirty-six years. Admitted to hospital July 7, 1892. The patient has a bubo in the left groin, with-

Continuation of Chart for Case V.

out any sign of venereal infection. He says that about twelve days ago he knocked against a pump-handle aboard the vessel, and he thinks that the bubo originated from that light blow in the groin. He is habitually constipated; looks cachectic. He received out-treatment two days ago and a cathartic was given him, but without effect. A mild cathartic and a tonic of iron, quinine, and strychnine given. Bubo poulticed.

July 8th.—It turns out that the patient has fever, of malarial type, which is probably the cause of the bubo, rather than the light blow in the groin ascribed by him as the cause. Previous medicine stopped and quinine sulphate ordered in ten-grain doses at 6, 7, and 8 A. M. daily (to-day at 9 and 10 A. M.).

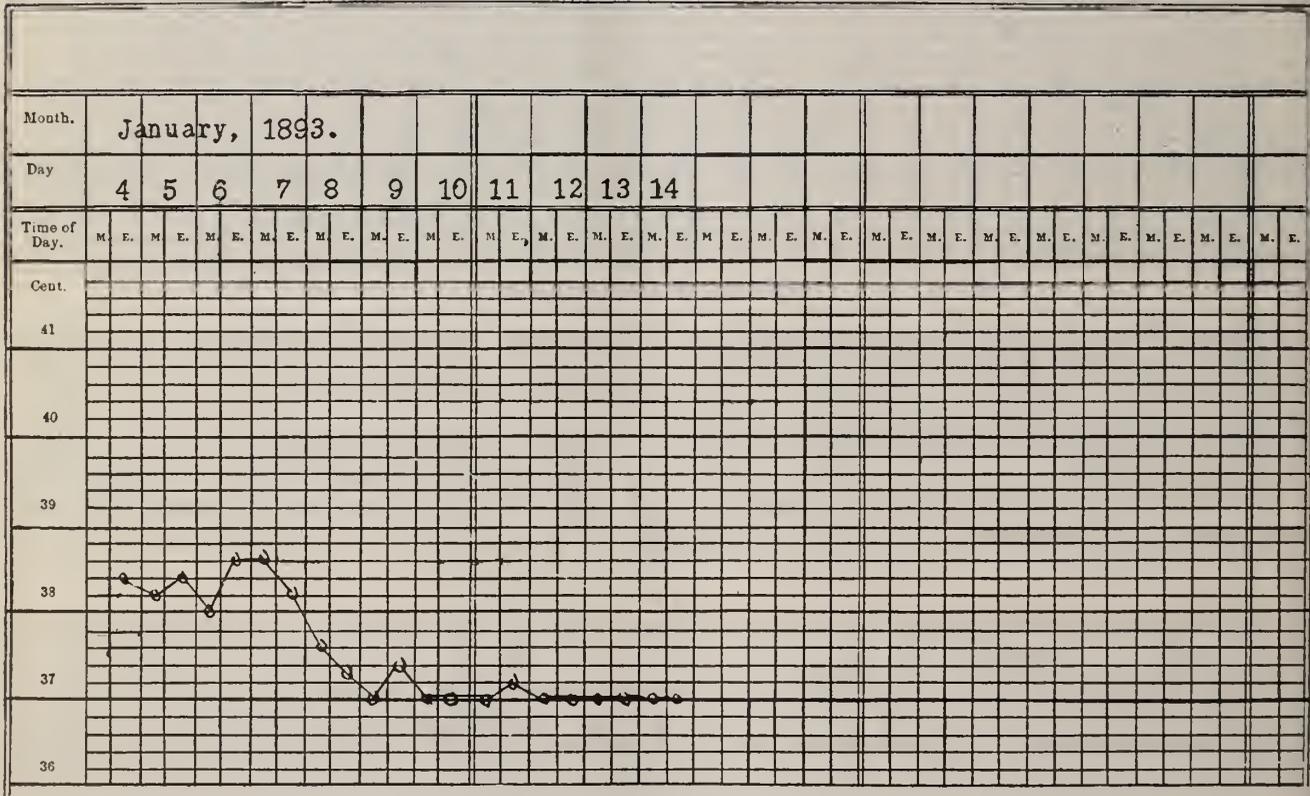

July 9th.—Stramonium ointment applied to bubo instead of poultice.

July 11th.—Fever has increased in spite of quinine,

August 22d.—Discharged, recovered.

A week later the patient was seen and had a slight return of fever. Tonics were given. Hospital treatment was not required.

CASE VI.—Observed at Galveston. A native of Denmark, aged thirty years. Admitted to hospital January 4, 1893. Patient has a large inflamed bubo in the left groin, which has been fifteen days in reaching its present condition. He has no sign of any venereal trouble and gives no history of such disease. He received treatment in this hospital for intermittent malarial fever from November 24 to December 2, 1892. Says he has had a feeling of fever every night for nine days past. Temperature on admission, 38.4° C. Stramonium ointment applied to bubo and Fowler's solution administered internally.

Temperature Chart for Case VI.

which is therefore stopped. ℞ Liq. potass. arsenitis, three drops t. i. d., increasing one drop daily till eight are reached.

July 12th.—Applications to bubo stopped.

July 16th.—Fever has become intermittent and quotidian.

July 21st.—Slight tendency to diarrhoea has succeeded to inactivity of bowels.

July 24th.—Fowler's solution stopped and a tonic of arsenic, strychnine, quinine, and tincture of iron given.

July 26th.—Bubo disappearing.

August 2d.—Some return of fever since July 29th. Previous medicines stopped and treatment with quinine resumed.

August 7th.—Quinine bisulphate and capsicum substituted for quinine sulphate alone.

August 10th.—Quinine and capsicum stopped and Fowler's solution given again.

August 18th.—Improving rapidly.

January 5th.—Bowels inactive; calomel cathartic given.

January 6th.—Treatment with quinine sulphate added to that with arsenic.

January 8th.—Application to bubo stopped.

January 9th.—Temperature normal.

January 11th.—Quinine stopped.

January 12th.—Fowler's solution stopped and tincture of iron and strychnine given.

January 15th.—Fever continuously absent, but bubo increasing in size. Poultice applied.

January 20th.—A change made to stramonium ointment locally.

January 23d.—Bubo is very tender and is softening superficially.

January 27th.—Tincture of iodine substituted for stramonium ointment locally.

January 31st.—The bubo was opened, but only blood was discharged from it.

February 2d.—No suppuration has taken place from the bubo and the wound is closed.

February 5th.—The swelling in the groin is decreasing in size and becoming less tender.

February 8th.—Discharged, recovered.

The cases are reported as they were recorded from day to day, which seems the most practicable way of showing their character. Besides the foregoing, I observed others at Galveston, of which I have no notes, and one or two at Memphis, Tenn. I have lately seen a case at New York, in the person of a sailor running between this port and Havana, but, unfortunately, only one examination of his blood was made before quinine was administered, and as that examination was not entirely satisfactory I omit reporting the case in detail. Free pigment granules were seen, but the plasmodium itself was not captured in that single search. I hope the attention of other observers will be attracted and that cases will be reported in which a thorough examination of the blood has been made. Such reports are most likely to come from tropical or subtropical regions.

In *Public Health Reports* for May 3, 1901, a report by Assistant Surgeon Stansfield, U. S. Marine-Hospital Service, from Cebu, Philippine Islands, mentions the existence in that island of a large number of cases of mild fever, rarely fatal, accompanied by glandular enlargement. It will be interesting to know what these cases prove to be on investigation.

Our Subscribers' Discussions.

I.

WHAT IS THE BEST WAY OF TREATING THE STUMP OF THE UMBILICAL CORD?

1. *Dr. Clarence L. Kilbourn, of New Haven, Conn.* (who takes the prize), sends the following:

Preface.—Always observe that simple rule laid down in every text-book, "Do not cut the cord until pulsation has ceased." This will, in nearly every case, prohibit hæmorrhage and perhaps lessen the chances of infection, which, fortunately, are not very great if modern technique is used. It allows the umbilical vessels to contract spontaneously, and this they do very firmly if left alone a few moments. There are contraindications, of course, such as uterine hæmorrhage or asphyxia of the mother, where immediate expulsion of the placenta is demanded. While waiting for pulsation to stop, have the nurse or attendant carefully bathe the child's abdomen, removing the excess of vernix caseosa. The child is held in a blanket and no unnecessary part of the body exposed.

Ligation.—It is well to recleanse and sterilize the hands before proceeding. Grasp the cord at a point two inches from the abdomen with an artery clamp and cut just beyond. Tie with narrow tape at the proximal side of the clamp or, if desired, at both proximal and distal. Loosen the grasp of the clamp and, if hæmorrhage is controlled by the ligature, remove it. If there is any oozing, cauterize the cut end thoroughly with

pure carbolic acid or, better still, with the Paquelin. This may also be done if there is any doubt of asepsis. If prejudice exists toward the cautery, apply instead an aqueous solution of suprarenal extract.

Dressing.—Make a thin pad of sterilized gauze, six or eight inches square and of several thicknesses. Place this over the child's abdomen, drawing the cord through a hole cut in the centre of the pad. Surround the stump with sterilized absorbent cotton, and over it place another gauze pad corresponding in size and thickness to the one underneath. Pass a few turns of gauze bandage about the body of the child, to keep the dressing in place. If the gauze irritates the skin, which is hardly possible, dust the abdomen lightly with lycopodium or zinc stearate.

Subsequent Treatment.—Change the dressing every other day. Dusting powders are of no particular value unless the cord has been lacerated. In that event the lacerated areas may be covered with a powder containing tannic acid. When the stump has become separated from the abdomen, discontinue the dressing and substitute a firm, but not excessively tight binder. This prevents, or at least limits, the chances of hernia and may be worn for several days. It should be removed during the daily bath, which should now include the umbilical region.

Hæmorrhage.—When obstinate or excessive hæmorrhage occurs at the *umbilicus*, there is but one decisive treatment. A strong silk suture is passed, by means of a curved needle, into the abdominal wall at one side of the umbilicus and brought out at the opposite side. It should include the edges of both recti muscles and be tied tightly over the navel. A similar suture is passed at right angles to the first. This crucial suture is effective. It is covered with a dry dressing of boric acid and is removed on the fourth or fifth day.

2. *Dr. John A. Lane, of Lolita, Cal.*, writes:

The following is the most simple, practical, and efficient method of treating the cord with which I am acquainted, and is the one I now use:

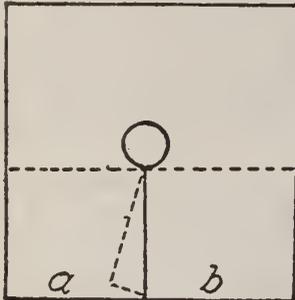

In preparing for the confinement, I have the nurse cut two strips of bobbin tape, eight or ten inches long, and sterilize them by boiling for twenty minutes, after which they are placed in a cup, previously sterilized by boiling, with some of the boiling water. The cup is covered with a fruit, fish, or tin cover and set aside until needed. Any antiseptic, such as bichloride, carbolic acid, etc., may be used in the water the tape is boiled in, but I rely more upon the boiling than upon an antiseptic.

When I sterilize the instruments which may be needed in the confinement, two hæmostatic forceps are included. After the sterilization the instruments are wrapped in a sterilized towel and placed on a stand at the side of the bed.

As soon as the baby is born its mouth is washed out with boric-acid solution or plain boiled water and respiration established. Sufficient time is allowed for the placental blood to pass into the baby; then the cord is clamped in two places with the hæmostatic forceps and cut between them. The baby is given to the nurse while I finish my part of the confinement, await the expulsion of the secundines, repair laceration, etc. This done, I have ample time in which to examine the baby and dress the cord.

The cord is squeezed between the fingers, about an inch from the body, then tied as tightly as possible with

one of the tapes. It is now cut a quarter of an inch externally to the tape with sterilized scissors. After the baby is washed, care being taken not to get the cord or the skin in the neighborhood wet, I conclude the dressing of the stump. A piece of sterilized old linen or aseptic gauze, four inches square, is cut as in the illustration. If gauze is used, three or four thicknesses are necessary.

The horizontal dotted line shows the fold. The hole in the centre is of about the size of the cord. This fits very well around the stump, but by causing *B* to overlap *A*, it will fit exactly.

A powder composed of one part of salicylic acid and fifteen parts of starch is dusted thickly on the stump and worked down in the crevices at the attachment of the cord. The cloth is now folded over the cord. First the lower part is folded, then the sides. This removes the stump as far as possible from the genitals and minimizes the danger of contamination of the dressings from the discharges.

The baby is now dressed. In bathing the child, the nurse is instructed to avoid wetting the dressing. If any moisture shows through the dressing, more of the powder may be applied. In four or five days the cord drops, leaving a healed umbilicus.

The advantages of this method are: 1. Its simplicity. 2. The cord encircling the neck does not interfere with the treatment at all. 3. There is no haste in tying the cord and no hæmorrhage from imperfect tying. 4. The material may be had in any house, with the exception of the forceps and powder. The forceps the doctor usually has in his emergency "grip." The powder may be sent as soon as possible and the nurse apply it as directed. 5. Efficiency. I have had no stumps remaining unusually long, as often happens with other stronger antiseptics, and I have had no infections.

3. Dr. Charles E. B. Flagg, Captain and Assistant Surgeon, U. S. Army, writes from Fort Grant, Arizona:

At the birth of the child, at once or when the cord ceases pulsating, a long-jawed artery forceps is applied at the junction of the skin and cord and another forceps to the cord nearer the placenta. The cord is severed between these forceps. The child is put aside in aseptic wrappings until the necessary attention has been given the mother.

The child is then placed on a table in a good light, the field of operation bared, sponged with a 1-to-4,000 solution of corrosive sublimate, and surrounded with sterile towels or gauze. A piece of gauze, with a hole or slit in the centre, answers well. The operator's hands are aseptic. The cord is then severed close to the edge of the forceps on the stump, the edge farthest from the skin of the child, or the cord may be cut here in the first instance. The vessels are then separately seized with other artery forceps, the forceps embracing the cord re-

moved, and the vessels then stripped up toward the abdomen and separately ligated with fine catgut. The vessels retract when liberated from the forceps. The remainder of the cord, up to the skin margin, is then cut away, the wound is then sponged with bichloride-of-mercury solution and a pad of sterile gauze, held in place by a sterile binder, applied.

Appliances Needed.—Sterile gauze, catgut, artery forceps, scissors, and an antiseptic solution. A clamp that I have devised may be used in place of the artery forceps nearest the child, but it is not necessary and possesses no great advantage over the forceps.

Requirements on the Part of the Operator.—Aseptic technique and ability to ligate blood-vessels, supposed to be taught to every medical student before graduation. Ligation is especially easy in these cases, as the vessels stand out with great distinctness in the gelatinous cord and can easily be separated from it.

Advantages.—A sterile wound, with nothing to slough away and no dead or half-dead tissue to act as a culture medium.

Absolute security against bleeding.

No after-treatment.

Healing in from three to five days.

Lessened danger of umbilical hernia in a wound healing *per primam* than in one healing by granulation.

It is maintained by some obstetricians of repute that the cord will not bleed even though the cord or vessels are not tied. Under these circumstances I have had one case of hæmorrhage. It was arrested by suturing.

In place of ligating the vessels, I have sutured them through the skin margin, beneath and before removing the forceps. A doubled continuous suture is used and is cut in two places and tied in three knots, as illustrated.

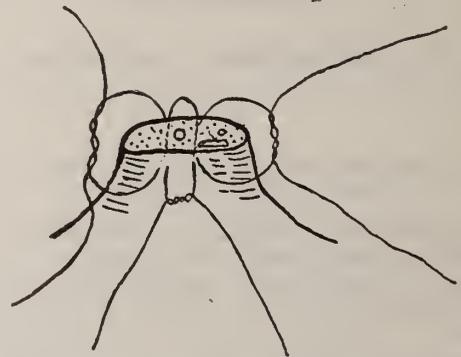

Diagram by Hospital Steward Lewis J. Schmidt, U. S. Army, showing method of suturing umbilical cord. A continuous doubled suture is applied, cut in two places, and tied as indicated above.

Bleeding may possibly occur in this method through retraction of the vessels, as the ligatures are not directly on the vessels, but have skin intervening.

I have amputated the cord at the skin margin since 1893. (See *Medical News*, 1897; also *Is a Sloughing Process at the Child's Navel Consistent with Asepsis in Childbed?* by Robert L. Dickinson, M. D., New York, *American Journal of Obstetrics*, December, 1898, and June, 1899.)

4. Dr. Emile Aronson, of Dallas, Tex., writes:

The principles of asepsis and antiseptics which control at present every field of surgery, also hold good for the physician engaged in obstetrical work. The time has passed when a pair of rusty old scissors of grandma's and some black or white cotton thread were good enough

to ligate the cord; such procedures were frequently the cause of septic infection of the new-born. The time-honored practice of wrapping the stump in a linen rag soaked in olive oil, or even carbolated oil, has also fallen into deserved disgrace and oblivion, and the principle of surgery to create a sterile wound with as little chance as possible for the development of pathogenic bacteria is now carried out by every conscientious and progressive physician and, let us hope, by every intelligent midwife.

Experience has taught that the best time to ligate the cord is about two or three minutes after birth of the child. We then inspect the cord, and if the same appears to be large, *i. e.*, if it contains a large amount of Wharton's jelly, we try to press it away before applying the ligatures.

The best material for the ligatures is surgeon's silk, No. 9, or silk gut, which, together with dressing scissors, has to be sterilized beforehand. Two ligatures are applied, one about one inch from the umbilicus of the child, and the second one about an inch from the first one, toward the placenta. The ligatures are drawn tight and the cord is cut slowly between the ligature, the physician taking care not to cut too close to the first ligature, to avoid slipping of the same and the necessity of applying another ligature.

The stump is then inspected as to whether it is bleeding or not, and, if it is not bleeding, wrapped in absorbent cotton. The nurse then bathes, cleans, and dresses the infant and then begins the toilet of the stump, *i. e.*, the stump is again inspected, to see if it is bleeding or if the ligature has got loose or slipped, and if it is found in order, dried thoroughly; a piece of aseptic gauze with a hole for the stump is then slipped over it and a dry dressing powder applied. One or two layers of antiseptic cotton are wrapped around the stump, which is then placed upward and to the child's right, and a well-fitting flannel bandage is wrapped around the child's abdomen. Of late, alcohol has been recommended instead of the dry dressing powder, the advocates of the alcohol alleging for it better antiseptic powers and quicker mummification of the stump.

The abdominal bandage is renewed daily; the nurse is to be instructed to avoid pulling or mistreatment of the stump; if the cord was thin, the stump will fall off in four to five days; if it was large, it might take more than five days, but, in any case, pulling at the dried-in stump to encourage its coming off is not to be recommended.

After the stump has fallen off, the young cicatrix ought to be covered with the dry dressing powder and ought to be protected from irritation by some gauze or cotton for several days to follow.

As a rare occurrence hæmorrhage may take place before the separation of the stump or after it has come off. In either case a needle, armed with silk, should be passed beneath the bleeding vessels and firmly tied, and pressure with gauze, cotton, and a tightly fitting abdominal binder applied. It would be well also to think in these desperate cases of the injection of gelatin and the administration of the suprarenal gland, but, believing that the discussion of this condition and such others as umbilical polypus is not entirely within the sphere of the question proposed, I shall limit myself to the remarks made.

5. *Dr. J. P. McQuillin, of Brooklyn, says:*

As the mortality from sepsis through the cord is estimated at from 3½ to 22 per cent., the necessity of using

more care in the dressing of the stump is apparent. I wish to call the attention of the profession to a simple and safe way to dress the stump of the cord. After notable pulsation has ceased in the lower portion of the cord, I take a small piece of silk braid, which has been standing in my antiseptic solution from the time I first examined the patient (I generally use creolin), and tie the cord tightly. I think it advisable to have the ligature aseptic, so that if the silk cuts into the cord there will be no danger of its absorbing septic matter from it. I tie the cord in two places and cut between the knots with a pair of sterilized scissors. I now sponge the end of the stump dry and cauterize it with full-strength carbolic acid. I now dress the stump with cotton, saturated with 96-per-cent. alcohol, changing the dressing once daily until the cord drops off. Any one using this method of dressing the umbilical cord will never have a case of septic poisoning.

6. *Dr. F. M. Wood, of Calumet, Mich., sends this:*

The stump of the umbilical cord is the most frequent source of infection in the infant; it is therefore desirable to perfect a method of treating it that will be surgically clean and at the same time simple and easy of application. The following method has proved efficient in the practice of the author: The cord is first cut short, an inch to an inch and a half in length, so that as little will be left as possible, in order that it may dry rapidly and come away quickly. It is then tied with a piece of sterile tape. The following has been found convenient and easy of application: The margin of a gauze sponge is torn off on the side of the selvage; this answers as a very strong and easily tied piece of tape, which is at the same time sterile and quickly obtained. Next, the abdomen of the child should be cleansed as follows: The cord is held with a piece of sterile gauze, and the abdomen washed with green soap and warm water; it is then dried with sterile gauze and again washed with a 1-to-1,000 mercuric-chloride solution. Care should be taken during the washing not to wet the cord or its base, keeping it well covered with the gauze, so that it may be perfectly dry when the dressing is complete, thus favoring early desiccation. Now take a small gauze sponge and fold it over once in the middle, cut a round hole of the size of the cord in its centre, using sterile scissors, pass the cord through this hole and envelop it in the gauze; the cord is thus left in a covering of gauze shaped like a funnel, the mouth of the funnel being at the base of the cord. The cord is then dusted with equal parts of boric acid and fine talcum, or with one part of salicylic acid and nineteen parts of starch. The same powder is applied also to the base of the cord. The cord is then laid so that it points toward the chin, so as to avoid hanging down and closer proximity to the excretions. It is then covered with a pad of sterile absorbent cotton. The abdominal binder is then put on; this should be of soft cotton flannel, and wide enough to reach from the hips to the axillæ; it should not be hemmed at the edges, as hems cause pressure and discomfort to the child. It is passed in two turns around the body of the child and pinned comfortably tight with safety pins, just tight enough so as not to embarrass the breathing of the child and still keep the dressing in place. Advise the mother not to allow the binder to become wet or soiled, which can be avoided by watching and frequently changing the diapers. Lastly, the cord should be inspected daily and dressed every other day with the dusting powder, clean gauze being applied when the previous dressing has become soiled. The hands of the attendant, the dress-

ings throughout, and all instruments used should be surgically aseptic; thus and only thus can the dangers of infection at this vulnerable point be avoided.

7. *Dr. Samuel Floersheim, of New York*, writes as follows:

It has been a routine method to place a short ligature around the umbilical cord about four inches from the umbilicus. This ligature is to prevent hæmorrhage from the placental end of the cord in case twins are present, and also for cleanliness. A second and long ligature is tied snugly about three inches from the umbilicus. This done, the umbilical cord is cut between the two ligatures, the placental end being allowed to drop down and the umbilical end cleansed and examined for any possibility of a hæmorrhage. If no hæmorrhage is found, the end of the cord is then turned inward toward the abdomen of the child, the two long free ends of the ligature are taken up, placed around the umbilical cord about half an inch from the umbilicus and tied tightly. This gives two ligatures to the cord and insures a safe procedure against primary and secondary hæmorrhage.

I have not found it necessary to strip the cord. There are many powders that can be used to dust on the stump to dry it. The one that has given the best satisfaction is stearate of zinc, plain, dusted on the abdomen around the umbilicus, a piece of sterile linen or thin, soft muslin with a perforation nearer to one end, through which the stump of the cord is placed and laid on the linen or muslin, the powdered stearate of zinc dusted on till it completely covers it, the linen folded over the cord and upon itself to prevent the powder from falling away from the cord.

Should infection of the cord take place, it is thoroughly washed in a 1-to-1,000 bichloride-of-mercury solution or in a 1-to-50 carbolic solution, dried and an antiseptic powder dusted on the cord, covered by a piece of iodoform or bichloride gauze, and a snug bandage applied. The cord, when infection has taken place, should be treated twice daily till all signs of pus have disappeared.

After the stump has fallen off and the umbilicus seems to be healing, the stearate of zinc powder is all that is necessary to dust on until the wound is healed.

If the umbilicus does not heal, but is granular and exuding fluid, it is thoroughly washed with tincture of green soap, rinsed with sterile water, thoroughly dried with sterile gauze, and a few drops of warm castor oil applied (and repeated about four times a day), a sterile gauze pad placed on the oil and a bandage in turn to hold the pad and oil in place.

When the stump of the cord has dropped off and hæmorrhage occurs, the suprarenal powder, dusted on the bleeding surface, covered by a pad of gauze of the size of a 25-cent piece and held in place by a snugly tied bandage, has succeeded in checking the hæmorrhage. The powdered suprarenal is washed off in half an hour to prevent infection. Oftentimes simply placing a small pad on the bleeding point and using finger pressure for a few moments or applying a bandage succeeds in controlling the hæmorrhage.

When granulations spring up from the umbilical wound or growths occur after the stump of the cord has fallen off, they are quickly and neatly removed by a pair of scissors. Pressure is then applied for a few moments to check the hæmorrhage and an antiseptic powder is dusted on the raw surface and a bandage applied. It is redressed daily till healed.

8. *Dr. Arthur H. Longstreet, of Brooklyn*, says:

Preparations.—I would recommend the procuring of a supply of $\frac{1}{16}$ -inch cotton tape, cutting it up into ten-inch strips, and sterilizing; to be carried in a suitable container and at the bedside dropped into a bichloride or carbolic solution to insure asepsis. This tape is strong, with ordinary precaution does not cut the tissues, is as sterile as silk, is more easily handled than catgut, and is the ideal ligature for this work.

Treatment.—Taking it for granted that the mother needs no particular attention (of course, if she does, the child can wait), we proceed with the treatment of the cord of the new-born. If the child is robust and crying lustily, the cord may be cut immediately; but if not so, wait until the pulsations have practically stopped. By waiting a few minutes, the child will tend to be more robust, not essentially on account of the possible addition of a few ounces of blood, but this enables a good pulmonary circulation to be established, from a combination of maternal and infant's blood current. With thumb and forefinger displace Wharton's gelatin for about two inches from the umbilicus and apply two ligatures, one about an inch and a half from the child's body and the other farther away, and cut between them. When the child is washed, see that the stump is thoroughly clean and wiped dry, then wrap the stump in a moderately thin layer of sterilized or borated absorbent cotton and apply a warm bandage, light in weight and not too tight. The double ligature prevents any complication, such as possible hæmorrhage in case of twins, etc.

When the cord is large or there seems to be a tendency to hernia, it is often a good plan to make a second ligation close to the child's body. This procedure lessens the amount of tissue to dry up and favors absorption, in addition to making a neater stump to handle and keep clean. The cotton may be changed or partially renewed each morning at the child's bath for the few days elapsing before the cord withers completely and drops off.

Cauterization is not needed where the stump is treated aseptically and antiseptically. A greasy rag or piece of burnt linen to wrap the stump in (which, strange to say, is still followed in some quarters) is an abomination.

If there should be some slight inflammation or irritation at the umbilicus either before or after the cord drops, or the parts keep moist, apply the following as a dusting powder after bathing and wiping dry:

℞ Powdered salicylic acid 1 part;
Starch 8 parts.
M.

9. *Dr. J. M. Kennedy, of Knoxville, Tenn.*, contributes the following:

The stump, having been washed and dried, should be enveloped in absorbent cotton and laid flat on the body of the child, pointing upward. The belly-band, four inches wide and long enough to go around the child three times, made of thin flannel in winter and of gauze bandage in summer, should be applied, the first turn above, but overlapping, the umbilicus; the second turn below, but also overlapping, and the third and last turn directly over the umbilicus. The end of the band should be fastened with half-inch strips of adhesive plaster. The band should be removed daily, or oftener if necessary, soiled cotton around the cord picked off, fresh cotton applied, and the binder replaced as before. When the cord is detached, the umbilicus should be

kept clean with pure warm water and dry with absorbent cotton. The belly-band should be kept on four weeks.

This dressing protects the parts from injury and infection, gives support to the umbilicus and abdominal organs, receives exudation from the cord, prevents the cord from adhering to the dress or skin of the child, and meets every indication, and I know of no objection to it.

If no dressing is applied, as has been occasionally suggested, the stump becomes hard and dry, is liable to be pulled by the clothing and prematurely detached, and is a mechanical irritant, and the part is not protected from infection. The ordinary folded linen, with a slit or hole in the middle, is apt to irritate by rubbing or chafing the base of the stump, and is not sufficiently absorbent. Oils are heating and sometimes irritating, powders are often both chemically and mechanically irritating, and neither oils nor powders can be rendered germicidal without being local irritants.

10. Dr. Z. E. Lewis, of New Rochelle, N. Y., furnishes the following:

I am not sure that the phraseology of this question does not bar me from its discussion, for how can a man profess to propound the "best" way who has not tried all ways in forming his judgment? And I have not that qualification. But if it is pertinent to state a method which thirty-five years' use, without the discovery of a single urgent drawback, has sanctioned, then I am in order in relating what I venture to denominate a sufficiently good method, having at least these elements of a "best way," that it is simple, that the necessary materials are always easily obtainable, and that the stupidest woman can carry out its details.

Before a "stump" can be "treated," it must be made, and I make it by tying the cord, at a distance of half an inch to an inch from the infant, with any clean cotton or linen tie which may be provided, most often the common white string of the shops. (I use the word "clean" in the ordinary lay acceptance.) The tying is tight enough to completely strangle the cord and to preclude slipping. The cord is then severed just outside the ligature. There is the stump.

After the babe has been washed, I insert the stump through a hole—just sufficiently large to admit it—in a pad made of from four to eight thicknesses of clean, soft white cloth (preferably linen, though cotton often has to be used) and then fold the pad so as to enclose the stump and make it lie flat on the belly, pointing upward and to the baby's left, where it is confined by the binder. This completes the initial treatment of the stump of the cord.

The remaining treatment consists chiefly in letting alone. I direct that the dressing shall be disturbed as little as possible in the necessary adjustments and washings, and shall on no account be allowed to become wet. The primary object is to have the cord dry into the dressing. If the baby's comfort requires that it be further protected in the drying, this object is attained by sliding a fresh pad of sufficient thickness under the first pad, with as little disturbing motion as possible. In due time the stump in its dressings comes away, leaving a perfectly healed navel.

The points are these: A short stump; a clean pad, thick enough to absorb the fluids of the stump; a hole small enough to secure against friction on the stump, that its position may not be disturbed in the folding and handling; no wetting of the pad; and a fair amount of immobility till the stump separates.

Therapeutical Notes.

Suggestion in the Treatment of Uncontrollable Vomiting.—Dr. Triantaphyllides (*Grèce médicale*, April; *Lancet*, May 25th), of Batoum, records a case of uncontrollable vomiting treated by suggestion. The patient was thirty years of age and in the first month of her seventh pregnancy. Unsuccessful attempts to induce premature labor had been made. Dr. Triantaphyllides, on taking charge of the case, assured her that abortion had taken place and that the uterus was empty. He stopped all local treatment and gave bread pills every three hours. The vomiting soon ceased almost entirely. Labor followed at term.

Santonin (Santonin Acid) in Tabetic Pains.—Negro (*Giornale della reale Accademia di medicina di Torino*, February; *British Medical Journal*, May 18th) has tried santonin with success in the treatment of the lightning pains of tabes. Of the 11 cases in which the drug was tried, 8 were decidedly relieved, 2 temporarily relieved, and 1 unaffected. At first the author gave 15 grains in three doses, at intervals of three hours, and in subsequent attacks began with 10 grains, 5 grains five hours later. The pain became decidedly less in three hours after the first dose, and completely ceased two hours after the second dose. So far the author has only administered it during the crisis, not in the intervals. None of the patients had this treatment more than four or five times in the course of two or three months.

The Treatment of Furuncles.—According to the *New York State Journal of Medicine* for April, Philipson recommends salicylic acid, in fifty-per-cent. strength, in the treatment of well-formed furuncles. The following paste is applicable for such conditions:

℞ Salicylic acid. 1 ounce;
Powdered starch. 1 drachm;
Lanoline. 1 ounce.

M. Sig.: Apply locally and change three or four times a day, in order to hasten the necrotic process.

When the core has been eliminated, he advises treatment to favor granulations. Minute furuncles may be checked by applying the following:

℞ Tincture of benzoin. 1 drachm;
Alcohol, enough to make. 3 ounces.

M. Sig.: Apply locally three times a day.

In generalized furunculosis the parts should receive a warm bath daily and then be rubbed with the following:

℞ Salicylic acid. 25 grains;
Vaseline, enough to make. 2 ounces.

M. Sig.: To be well rubbed in over the affected area.

Heat in the Treatment of Gonorrhœa.—The *Medical Press and Circular* for June 5th says that attention has recently been called to the fact that the therapeutical effects of irrigations of the urethra by Janet's method are greatly increased by employing the solutions of permanganate of potassium or other salt at a comparatively high temperature; indeed, it is confidently asserted that the temperature is of more importance than the chemical composition of the solution. The temperature should not be less than 98° F. and may advantageously be carried to 120° F. These hot injections are stated not to give rise to any untoward consequences.

NEW YORK, SATURDAY, JUNE 22, 1901.

THE PROPOSED EXCLUSION OF ALIEN
CONSUMPTIVES.

It is our conviction that the United States Bureau of Immigration, if it has really determined upon the course of indiscriminately excluding consumptive immigrants from the country, as has been announced, has been ill advised. As has been said publicly by Dr. S. A. Knopf, the indefatigable champion of everything that promises to conduce to our eventual mastery over tuberculous disease, a consumptive pauper may properly be denied admittance to our domain, but because he is sure to become a burden on the community in which he casts his lot, not because he is tuberculous. In our great southwestern resorts for consumptives, many a person has arrived with the disease in a decided, if not in an advanced, stage, and lived to become a valuable member of his adopted municipality or even of his adopted State, and that, too, without endangering any of its people. If a consumptive is conscientious and properly managed, he is sure not to become a source of danger, and the very fact of a consumptive's coming to this far-away country for the benefit of his health may almost be taken as *prima facie* evidence of his conscientiousness and of his readiness to be guided by medical advice.

So little do we fear retaliation by European nations, however, that, if the short-sighted policy of our own bureau is carried out, we should rather welcome it, for then the American money that is annually spent in European resorts for the tuberculous would go toward enabling our own people to perfect their appliances for supplementing climatic influences in the treatment of consumptives. What the people need to be taught—and they have already partly learned the lesson—is, not that pulmonary consumption is a monster to be fled from, but that it is a danger that can be effectively

overcome. Even if this were not true, it remains a fact that the policy of selfishness and inhumanity, pursued to the end, rarely if ever proves to be for the general welfare of those who follow it. We of the East should protest loudly if Colorado, Arizona, New Mexico, and California forbade our consumptives to enter their limits; let us as a nation, then, pause to contemplate the matter of exclusion from the foreign consumptive's point of view, and throw our sanitary resources open to the world as we long ago made our lands and our industrial facilities free to all worthy comers.

INFLUENZA AS A PROMOTER OF SUICIDE.

THREE recent occurrences, the deaths of Dr. Guernsey and the Rev. Mr. Babcock, of New York, and of Dr. William H. Daly, of Pittsburgh, by suicide after an attack of influenza, can hardly fail, we should say, to impress upon the medical profession and upon the general public the dangerous character of the emotional perversion that often follows in the wake of that disease and lasts sometimes for a very long period—as long as two years, to our certain knowledge, in some instances. All three of the victims whose names we have mentioned were men in the prime of a successful and creditable career, with every reason to look forward to many more years of usefulness and happiness, but the wretched dejection consequent on their ailment seized upon them and overthrew their mental balance. Even men who are naturally the greatest of optimists—optimistic almost to the extent of being visionary—are caught in the toils of this dreadful melancholy, and in too many cases yield to the suicidal tendency. The intellectual faculties, so far as we have observed, are but little if at all impaired; so soon as he has recovered his physical strength, and even sooner, the subject is able to do his ordinary amount of intellectual work and do it as well as before. But any occasion of emotional disturbance, no matter how trifling, upsets him, makes him lacrymose, and plunges him into the despair that so often leads to suicide.

When we add to the vast physical damage wrought by influenza, directly or indirectly, this melancholic psychological sequela, we have some idea of the death-dealing power of the disease. In the absence of any specific curative treatment, we must bend our efforts toward restricting the spread of the infection—with no great prospect of substantial success, it must be admitted—and toward preventing patients who are apparently con-

valescent from resuming their ordinary course of life too soon, having first, if we are able, prevailed upon them to give up work and take to bed in the incipency of the ailment. From the particular point of view of the not uncommon suicidal tendency in the after-melancholy, we may well urge upon the friends of convalescents who are affected with this sequela unusual watchfulness, even to the degree of rousing the patients' resentment, which, indeed, might prove a wholesome restorative.

THE TREATMENT OF SQUINT.

IN the May number of the *Archives of Ophthalmology* Dr. Herbert Wright Wootton has published a strong paper on the correction of strabismus, or squint, by the advancement of the opposing muscle as the primary operation, instead of the tenotomy of the contracted muscle which is commonly performed. This operation, first advocated by Landolt, of Paris, certainly offers important advantages over the older method which deserve the attention of every surgeon who may be called upon to operate in such cases. For the most part surgeons will agree with Dr. Wootton when he says: "Tenotomies, as primary operations, particularly in convergent cases, are at best hazardous procedures. Apparent parallelism, for the time being, is frequently obtained, but almost always with great sacrifice of the power of convergence.

The operation, one might almost say, has attempted to cure the causative factor, the hypermetropia, by superadding a pathological condition, a relative insufficiency of convergence, ignoring the fact that an excess of converging power is a normal condition with an uncorrected hypermetropia." In the great majority of cases the only benefit obtained by tenotomies is an improvement in the cosmetic appearance; indeed, only too often this is the only benefit sought for. A careful examination reveals the fact that the parallelism is not perfect, and time may demonstrate it to be temporary. It is not an infrequent occurrence to have divergence of the eyes appear some months or years after the internal recti have been tenotomized for the correction of a convergent squint, and this is a weighty testimony to the weakened condition of the tenotomized muscles which in a measure explains why binocular single vision, or the conjoint use of the two eyes, is so seldom obtained and maintained after such an operation. But when the eyes have been straightened by the advancement of the tendons of the external recti, in a case of concomitant convergent squint, without tenotomy of the internal recti, the cosmetic re-

sult is quite as good, while at the same time no function of the eye has been interfered with and its motility has not been lessened in any direction. Then if, when the correcting glasses are worn, the vision of each eye is good, there is a much better opportunity to obtain binocular single vision than after a tenotomy, and, if minor deviations exist, the eyes are in a good condition to have them recognized and corrected. These two considerations alone should be sufficient to command for this method its thorough and practical trial, at least in all cases of strabismus in which the vision of the two eyes even approaches equality.

THE SURGEON'S RIGHT TO DISCRETION AT OPERATIONS.

A VERY important and, as it seems to us, a very just and reasonable decision, was given in a Chicago court by Judge Kavanagh on June 18th. On June 7, 1897, Dr. Franklin H. Martin, of the Post-graduate Medical School and Hospital, Chicago, in the course of an operation on a patient under an anæsthetic, was unexpectedly confronted with conditions that appeared to him to demand another operation besides the one contemplated. Both were successfully performed, and the patient at the time suit was brought, four years later, was in good health. The action was brought by the patient against the hospital for the unauthorized performance of the un contemplated operation. For the defense the point was raised that conditions were found in the course of the operation which rendered the further operation essential to preserve the life of the patient, and the judge ruled that in acting without loss of time under such conditions the surgeon acted within his right. Of course, it is not contended by any one that a surgeon, having obtained the consent of a patient to one operation, should in addition perform another, however desirable in the patient's interest, that is only an operation of expediency; but it would be absurd to argue that, some sudden emergency arising, the surgeon has not discretion to do what is necessary to deal with it, as, for instance, by ligating at a distance the main trunk of an artery to check otherwise uncontrollable hæmorrhage; or, in the case of a malignant growth having ramifications beyond what the pre-operation diagnosis had established, the removal of other affected organs, or portions of organs, besides those whose removal was originally contemplated. It is, however, wise policy, whenever there is any reasonable probability of unexpected complications, to obtain the patient's prior consent to deal with any other conditions that may be found essentially connected with the proposed operation. An appeal has been threatened. We trust that the appeal court will sustain the eminently just decision of the lower court if appeal is actually taken in this case.

TROLLEY-CAR DANGERS.

It is satisfactory to learn that the Appellate Division has done something toward minimizing one of the many dangers to life that a long-suffering public endures at the hands of the trolley cars in New York. In the case of William F. Fay against the Metropolitan Street Railway Company, which had been dismissed in the court below, the court held that reasonable time to board a car must be afforded to the public; and that the contributory negligence alleged by the defendant company against the plaintiff did not hold good, because the plaintiff "having hold of the car, about to board it when the car suddenly started, there was presented an emergency which required the exercise of judgment as to the best course to avoid being injured." Such exercise of judgment was, of course, rendered particularly difficult by the premature starting of the car, which, therefore, there could be no doubt, "was the proximate cause of the injury." What with the reckless speed at which cars are at times driven, especially at crossings and around curves, and the scant consideration afforded to passengers mounting or alighting, it is a wonder that there are not more serious accidents than actually occur.

THE DEFICIENCY IN ARMY SURGEONS.

THE contention of Surgeon-General Sternberg, that the provisions of the recent army act relating to the medical department, by increasing the establishment in the lower ranks without a proportional increment in the upper ranks, would keep physicians from entering the service, has been justified by the dissolution of the boards created to examine applicants for medical commissions in the army without their having been able to secure a sufficiency of candidates. The extent to which governments at large seem to ignore the judgment and superior knowledge of those of their higher executive officials as to the needs and otherwise of those portions of the public service over which those officials have been selected, presumably on account of their fitness, to rule, seems almost fatuous. The United States is by no means alone in this matter. A much more conspicuous example may be seen in the entire military administration, medical and otherwise, of Great Britain.

OUR SUBSCRIBERS' DISCUSSIONS.

IN this issue of the *Journal* we publish a few—all that we have space for—of the answers to our first prize question. We would again remind our subscribers that answers to our second question, *What is the best way of prescribing calomel as a purgative?* should reach us on or before July 10th, as was stated in our issue for May 11th. We will also now announce the third question, *How do you treat Colles's fracture of the radius?* Answers to the third question should reach us on or before August 12th.

News Items.

Society Meetings for the Coming Week:

- MONDAY, June 24. Cambridge, Massachusetts, Society for Medical Improvement; Baltimore Medical Association.
- TUESDAY, June 25: Buffalo Academy of Medicine (Section in Obstetrics and Gynecology); Richmond, Virginia, Academy of Medicine and Surgery.
- WEDNESDAY, June 26: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; American Microscopical Society of the City of New York; Auburn, N. Y., City Medical Association; Berkshire, Massachusetts, District Medical Society (Pittsfield); Philadelphia County Medical Society.
- THURSDAY, June 27: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Society for Neurology; Pathological Society of Philadelphia.
- FRIDAY, June 28: New York Society of German Physicians; Philadelphia Clinical Society; Philadelphia Laryngological Society.

Infectious Diseases in New York:

We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending June 15, 1901:

DISEASES.	Week end'g June 8		Week end'g June 15	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	30	5	28	8
Scarlet Fever.....	449	30	466	40
Cerebro-spinal meningitis	0	0	0	4
Measles.....	302	13	270	8
Diphtheria and croup...	241	48	244	39
Small-pox.....	86	16	102	11
Tuberculosis.....	226	152	243	141

Marine-Hospital Service:

Official List of the Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine Hospital Service for the fourteen days ending June 13, 1901:

- BREADY, J. E., Acting Assistant Surgeon. Granted leave of absence for one day from June 19th.
- DECKER, C. E., Assistant Surgeon. Granted leave of absence for ten days, on account of sickness.
- ECROYD, HENRY, Acting Assistant Surgeon. Granted leave of absence for ten days from June 8th.
- KING, W. W., Assistant Surgeon. Granted leave of absence for four days.
- MASON, W. C., Acting Assistant Surgeon. Granted leave of absence for six days from June 23d.
- NYDEGGER, J. A., Passed Assistant Surgeon. Granted leave of absence for thirty days from June 8th.
- PETTUS, W. J., Surgeon. Granted leave of absence for three days from June 13th.
- SMYTH, F. R., Acting Assistant Surgeon. Leave of absence for three days granted him by the Bureau. Telegram of May 31, 1901, is revoked.
- SPRAGUE, E. K., Passed Assistant Surgeon. Granted leave of absence for thirty days from May 30th.
- STANTON, J. G., Acting Assistant Surgeon. Granted leave of absence for fifteen days from June 3d.
- WHITE, J. H., Surgeon. To report at Washington for conference.
- WICKES, H. W., Passed Assistant Surgeon. Granted leave of absence for four days from June 3d.
- WILLIAMS, L. L., Surgeon. Granted leave of absence for five days from June 8th.

Board Convened.

Board convened to meet at Washington on June 7, 1901, for the physical examination of an applicant for cadetship in the United States Revenue Cutter Service. Detail for the Board Passed Assistant Surgeon H. D. GEDDINGS, *Chairman*; Assistant Surgeon B. S. WARREN, *Recorder*.

Marine-Hospital Service Health Reports:

The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending June 15, 1901:

Small-pox—United States and Insular.

Douglass City, Alaska.....	May 25.....	5 cases.	
San Francisco, California....	May 25-June 1..	4 cases.	
Washington, District of Col..	May 30.....	1 case.	
Chicago, Illinois.....	June 1-9.....	6 cases.	
Michigan City, Indiana.....	June 3-10.....	2 cases.	
South Bend, Indiana.....	June 1-8.....	1 case.	
Wichita, Kansas.....	June 1-8.....	7 cases.	1 death.
New Orleans, Louisiana.....	June 1-9.....	5 cases.	1 death.
Shreveport, Louisiana.....	May 25-June 1..	2 cases.	
Portland, Maine.....	June 1-8.....	1 case.	
Baltimore, Maryland.....	June 1-8.....	1 case.	
Boston, Massachusetts.....	June 1-8.....	1 case.	
Fall River, Massachusetts...	June 1-8.....	1 case.	
Marlboro, Massachusetts.....	June 1-8.....	1 case.	
New Bedford, Massachusetts...	June 1-8.....	27 cases.	1 death.
Somerville, Massachusetts....	June 1-8.....	1 case.	
Detroit, Michigan.....	June 1-8.....	33 cases.	
West Bay City, Michigan.....	June 1-8.....	1 case.	
Winona, Minnesota.....	June 1-8.....	1 case.	
St. Louis, Missouri.....	May 26-June 2..	32 cases.	
Manchester, New Hampshire...	June 1-8.....	4 cases.	
New York, New York.....	June 1-8.....	86 cases.	16 deaths.
Cincinnati, Ohio.....	May 31-June 7..	5 cases.	
Cleveland, Ohio.....	June 1-8.....	30 cases.	
Toledo, Ohio.....	June 1-8.....	1 case.	
Lebanon, Pennsylvania.....	June 1-8.....	1 case.	
Philadelphia, Pennsylvania....	June 1-8.....		1 death.
Pittsburgh, Pennsylvania.....	June 1-8.....	5 cases.	
Providence, Rhode Island.....	June 1-8.....	1 case.	1 death.
Ogden, Utah.....	May 1-31.....	11 cases.	
Salt Lake City, Utah.....	June 1-8.....	4 cases.	
Tacoma, Washington.....	May 27-June 2..	1 case.	
Green Bay, Wisconsin.....	June 2-9.....	2 cases.	
Manila, Philippines.....	Apr. 13-20.....	9 cases.	
San Juan, Porto Rico.....	May 10..	Extinct;	8 cases on island.

Small-pox—Foreign.

Prague, Austria.....	May 13-25.....	3 cases.	
Antwerp, Belgium.....	May 18-25.....	3 cases.	1 death.
Pernambuco, Brazil.....	Apr. 1-15.....		27 deaths.
Hongkong, China.....	Apr. 22-27.....	7 cases.	5 deaths.
Panama, Colombia.....	May 27-June 3..	5 cases.	1 death.
Paris, France.....	May 18-25.....		15 deaths.
Glasgow, Great Britain.....	May 25-31.....	42 cases.	1 death.
Athens, Greece.....	May 18-25.....	2 cases.	
Calcutta, India.....	May 4-11.....		34 deaths.
Karachi, India.....	Apr. 28-May 12.	9 cases.	3 deaths.
Naples, Italy.....	May 19-26.....	161 cases.	28 deaths.
Nagasaki, Japan.....	May 6..	1 case on U. S. S. Indiana.	
Tokyo, Japan.....	May 11.....	3 cases.	
Winnipeg, Manitoba.....	May 25-June 1..	2 cases.	
Mexico City, Mexico.....	May 19-June 2..		3 deaths.
Odessa, Russia.....	May 11-26.....	9 cases.	1 death.
St. Petersburg, Russia.....	May 4-13.....	24 cases.	5 deaths.
Warsaw, Russia.....	May 4-11.....		8 deaths.

Yellow Fever.

Vera Cruz, Mexico.....	May 18-25.....		1 death.
------------------------	----------------	--	----------

Cholera.

Bombay, India.....	May 7-14.....		3 deaths.
Calcutta, India.....	May 4-11.....		47 deaths.

Plague—Foreign and Insular.

Cape Town, Africa.....	To Apr. 5.....	412 cases.	181 deaths.
Hongkong, China.....	Apr. 20-27.....	65 cases.	55 deaths.
Bombay, India.....	May 7-14.....		239 deaths.
Calcutta, India.....	May 4-11.....		134 deaths.
Karachi, India.....	Apr. 28-May 12.	657 cases.	563 deaths.
Formosa, Japan.....	{ May 18, increas- ing. From May 3-June 1..... }	2,157 cases.	
Manila, Philippines.....	Apr. 13-20.....	27 cases.	16 deaths.

Naval Intelligence:

Official List of Changes in the Medical Corps of the United States Navy for the Two Weeks ending June 15, 1901:

- ANDERSON, F. A., Assistant Surgeon. Ordered to the Naval Hospital, New York.
- BACKUS, J. W., Assistant Surgeon. Ordered to the Vermont.
- EVANS, S. G., Passed Assistant Surgeon. Detached from the *Monocacy* and ordered to the *Solace*.
- HARRIS, H. N. T., Surgeon. Detached from the *Albany* and ordered to the *Monocacy*.
- MAYERS, G. M., Assistant Surgeon. Ordered to the Pensacola Navy Yard, Florida.

MURPHY, J. F., Assistant Surgeon. Ordered to the Naval Academy, Annapolis.

WENTWORTH, A. R., Surgeon. Detached from the *Solace* and ordered to the *Albany*.

Army Intelligence:

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department of the United States Army from June 8 to 15, 1901:

- CARTER, W. FITZHUGH, Major and Surgeon, is granted leave of absence for twenty-one days, to take effect on or about June 14, 1901.
- DUTCHER, BASIL H., First Lieutenant and Assistant Surgeon. So much of Par. 12, S. O. 131, June 6, 1901, H. Q. A., as directs him to proceed to Fort Totten, New York, for duty, is amended so as to direct him to proceed to Fort Hancock, N. J., to relieve DEANE C. HOWARD, Captain and Assistant Surgeon.
- ERWIN, JAMES J., Captain and Assistant Surgeon, is honorably discharged, to take effect June 30, 1901.
- GRISWOLD, RICHARD S., Major and Surgeon, will proceed to San Francisco for transportation to Manila.
- HOWARD, DEANE C., Captain and Assistant Surgeon. So much of Par. 7, S. O. 2, January 3, 1901, as relates to him is amended so as to direct him to proceed to Havana, Cuba, upon his relief from duty at Fort Hancock by BASIL H. DUTCHER, First Lieutenant and Assistant Surgeon.
- KULP, JOHN S., Major and Surgeon. So much of Par. 24, S. O. 58, March 12, 1901, as assigns him to duty at Fort Hancock, N. J., is amended so as to direct him to proceed to New York for duty as attending surgeon and examiner of recruits, and as medical superintendent of the Army Transport Service in that city, to relieve WILLIAM D. CROSBY, Major and Surgeon, who will proceed to Fort McPherson, Georgia, for duty.
- MCCAW, WALTER D., Major and Surgeon, is detailed as a member of the board of medical officers appointed by Par. 12, S. O. 15, January 18, 1901, for the examination of candidates for admission to the Medical Corps of the Army, vice WILLIAM J. WAKEMAN, Major and Surgeon, who is relieved.

Changes of Address.—Dr. Joseph E. Lumbard, to Graham Court, Seventh Avenue and One Hundred and Sixteenth Street, New York; Dr. Edwin Ricketts, to No. 408 Broadway, Cincinnati, Ohio.

A New Laboratory Building for the Medical College of New York.—A four and five story laboratory building of brick, limestone, and terra cotta, 22.6 by 18.6, from plans by William Burnett Tuthill, is to be added to the Medical College of New York, at 17 and 19 East One Hundred and First Street. It is to cost \$40,000.

Hygienic Exhibition at Carlsbad.—Consul-General Guenther, at Frankfort, in a report to the State Department at Washington, D. C., says that a general exhibition of articles of hygiene of the sick room, of food and drink, and also of those pertaining to the entertainment and comfort of the traveling public, will be opened at Carlsbad on August 10th of this year.

Class Reunion of the Jefferson Medical College Graduates of the Year 1891.—Dr. Matthew F. Smith, editor of the *Texas Medical News*, calls upon all graduates of the Jefferson Medical College of 1891 to attend a meeting of the class, to be held in Philadelphia on June 28th and 29th. Dr. Smith's address is 101 West Sixth Street, Austin, Tex.

Colonel Forwood Placed in Charge of the Medical Department of the Army.—Colonel William H. Forwood, of the Medical Department, who has been in charge of the important medical depot station at San Francisco, has been assigned to Washington and placed in charge of the Medical Department of the army dur-

ing the absence of Surgeon-General Sternberg in the Philippines.

Yale University.—The annual address in medicine will be delivered by Professor Edmund B. Wilson, Ph. D., of Columbia University, on The Higher Claims of Minute Research in Biology and Medicine, in the College Street Hall, Yale University, on Tuesday, June 25th, at noon.

Physicians Held Guiltless of Malpractice.—The second trial of the action brought by Miss Lucy V. Kellen, a dressmaker, to recover \$60,000 damages from Dr. Morris Manges and Dr. Julius Rosenberg for performing an operation on her, as she alleged, unskillfully and without her consent, terminated, after a trial lasting several days, before Justice Bischoff and a jury in the Supreme Court, New York, in a verdict, on June 11th, in favor of the defendants. The former trial ended in a disagreement.

A Physician Missing.—We have been requested to ask for information concerning William Clifford McDonald, M. D., Harvard, '98, who left his home, in Lynn, Mass., for New York three months ago. He wrote of his arrival in New York and stated that he would write soon again. Since then nothing has been heard of him and his friends fear foul play. Dr. McDonald was a young man, six feet tall, weight 200 pounds, with a dark-brown mustache. Any information will be gladly received at the home of his friend, Dr. James Keown, 23 Irson Street, Lynn, Mass.

Presentation to Dr. Charles K. Briddon.—On Friday evening, June 14th, the Alumni Association of the Presbyterian Hospital, New York, Dr. W. K. Simpson presiding, gave a complimentary dinner to Dr. Charles K. Briddon at the University Club, presenting him at the same time with a loving cup and an illuminated parchment testimonial signed by the members of the association in commemoration of his service of twenty-five years as attending surgeon to the hospital. The presentation address was delivered by Dr. Benjamin Hedges, of Plainfield, N. J. Responses were made by Dr. Briddon, members of the attending staff, and by each member present as the loving cup was passed.

The New York Hospital Distributes its Museum.—All the anatomical and pathological collections of the New York Hospital Museum have been given by the governors of the hospital to the medical colleges of New York, the Post-graduate Medical College, the New York University, the Bellevue Hospital Medical College, the Cornell University Medical College, and the College of Physicians and Surgeons. These institutions arranged among themselves for the division of the collections donated. It was thought that as no lectures were given at the New York Hospital, and the museum was maintained only for exhibition to visiting doctors and others interested, the specimens could be used to better advantage in connection with the work of educational institutions. Three years ago the hospital gave away its library for the same reason to the Academy of Medicine.

Tuberculosis Data is Sought by the New York State Department of Health.—Local health officers throughout the State have been requested by the State Department of Health to furnish a list of the number of per-

sons afflicted with consumption in their respective localities. The present purpose is not to acquire or obtain personal registry of these cases, nor to institute a system of sanitary inspection or isolation of consumptives, but to obtain with such accuracy as is possible a record of the number of persons in each municipality who at this time are subjects of this disease, to learn the locality of the disease, its distribution, and surroundings. The data thus collected will lead to more exact plans for its control. The knowledge will likewise be of great value in the discussion of the question of State care of consumptives and also in determining the death rate from this cause. A further report of the source of infection would also be valuable in the study of the aetiology of tuberculosis as well as of its prophylaxis.

A State Laboratory for New York.—A State laboratory is to be established at Albany, N. Y., at once by the State health commissioner, Daniel Lewis, under an appropriation of \$20,000, made by the last legislature. In order to facilitate the prompt commencement of the work contemplated, pending the construction of the new laboratory building, Dr. Lewis has arranged for the State's work to be performed at the Bender Laboratory. The State Laboratory will be in charge of Dr. Blumer, the pathologist for the State health department. The laboratory is to be utilized in connection with the legislature's direction so that the State Department of Health shall conduct the work of the manufacture of tetanus, streptococcus, and diphtheria antitoxine, and to conduct further investigations of serum therapy in tuberculosis, typhoid fever, and kindred diseases.

A Chicago Judge's Decision in a Christian Science Case.—Judge Tuthill, of the Juvenile Court, Chicago, on June 11th committed John Chamberlain, who, while suffering from a shrunken leg, was taken out of the custody of his mother, a Christian Scientist, to the Crippled Children's Home. According to the view of Judge Tuthill, adults are at liberty to use medicine or "faith cure," or any other means to fight disease. Children, however, according to his belief, must legally be given that sort of cure, which, according to generally accepted notions, is needed. When the parents refuse to call in a physician, and when the child is subjected to long-continued suffering, Judge Tuthill holds, it is time for the court to step in and demand protection for the young. The parents failing to afford it, institutions should care for the children.

"Christian Science" Death in Brooklyn to be Investigated by Authorities.—District Attorney John F. Clarke, of Brooklyn, with the officials of the local health department, may, if the evidence they expect is forthcoming, have the parents of Francis Nixon Fletcher before the Kings County Grand Jury and endeavor to obtain an indictment for manslaughter in the second degree. Young Fletcher died in the home of his father, on June 5th. A wrong date in the death certificate, which was signed by a woman practitioner, Dr. A. E. Morris, excited the suspicion of the authorities, who were led to believe that the boy died while under treatment by Christian Scientists. The legal question as to whether or not Christian Scientists, who, by failing to call a physician, make themselves responsible for a death, can be held for manslaughter on the ground of culpable negligence, will, it is believed, be threshed out before the Grand Jury. Through Dr. Byrne, the health department is prepared to carry the matter to a final issue.

The London Tuberculosis Congress.—The British Congress on Tuberculosis, which is to be held in London on July 22d and three following days, promises to be the occasion of an important gathering. There will be four sections: (1) State and municipal; (2) medical, including climatology and sanatoria; (3) pathology, including bacteriology; and (4), veterinary (tuberculosis in animals). Professor Koch, Dr. Roux, Sir Lauder Brunton, Sir Richard Douglas Powell, Professor Dewar, Sir William Broadbent, Sir Dyce Duckworth, and Professor Allbutt are a few of those who have intimated their intention of being present and reading papers or taking part in the discussions. A considerable number of American physicians are expected to attend the congress and the meeting of the British Medical Association, and for their convenience a special excursion, leaving New York on July 10th by the Red Star Line steamer *Zeeland*, has been arranged by Gage & Sons. The twenty-nine-day trip is to cost \$238 and will include first cabin on Atlantic steamers, second class on European railroads, baggage transfer, hotels, fees, etc. The programme is as follows: Paris from July 19th to 22d; London, for the congress, 23d to 28th; Cheltenham, for the British Medical Association's meeting, from July 29th to August 1st, when the party will sail from Liverpool, arriving at Boston August 8th. For a slight extra cost the entire meeting of the British Medical Association can be attended. Dr. William Osler writes to us, urging the desirability of as strong a contingent as possible of American physicians joining in the congress. Those who wish to do so, should send their names, enclosing five dollars, to Dr. St. Clair Thomson, 20 Hanover Square, London, W., England.

The Right to a Reasonable Time for Boarding a Car.—While about to board a downtown Broadway car, a man took hold of the upright rail and waited for those ahead of him to get on. Just as he had his left foot on the step the car gave a sudden jerk. He was unable to get on, and so ran along with the car. There was some projection sticking out, obscuring a hole in the street, and into this hole the man fell. The dismissal of his suit for damages against the Metropolitan Street Railway Company has been held, on appeal to the Appellate Division, to be an error. "The defendant," said the court, "was bound to give the plaintiff a reasonable time to board the car, and the evidence would have justified finding that the defendant was negligent in that respect, nor do I think that the plaintiff was, as a matter of law, guilty of contributory negligence. Having hold of the car about to board it, when the car suddenly started, there was presented an emergency which required the exercise of judgment as to the best course to avoid being injured. If to avoid being thrown down by the sudden starting of the car, he held on to the car to steady himself until he could let go in safety, it was certainly not negligence as a matter of law. But for the existence of this trench in the roadway alongside of the track, which he had not observed, he would probably have escaped injury by adopting the course that he did, but his falling into the trench was caused by his being dragged along by the car. It seems to me that the question of contributory negligence was one for the jury. There can be no doubt that the starting of the car was the proximate cause of the injury. If the car had not started, the plaintiff could have got aboard in safety. It, however, started when he had hold of the car, and the sudden starting of the car carried him along with it, and if

he, to avoid falling, kept hold of the car until he could regain his equilibrium and in so doing was by the momentum of the car thrown into this trench, it was the sudden starting of the car and the motion contributed by the car to the plaintiff which caused him to fall into the hole, from which he sustained the injury for which he seeks to recover."

The Medical Society of New Jersey will hold its one hundred and thirty-fifth annual meeting at the Hathaway Inn, Deal Beach, N. J., on June 25th, 26th, and 27th. The following is the order of business:

Tuesday, 3 P. M.—Minutes of the last meeting, reports of officers, committees, and delegates, election of permanent delegates, announcement of committees by the president, the reception and acting upon applications for the degree of M. D., and nominations for honorary membership.

Tuesday Evening, 8 o'Clock.—Annual address by the president, Dr. J. D. McGill, of Jersey City, The Medico-legal Expert; Progress in State Medicine and Hygiene, by Dr. W. H. McGee, of Belvidere; Progress in Medicine and Therapeutics, by Dr. Dowling Benjamin, of Camden; Progress in Surgery, by Dr. Charles Young, of Newark; Progress in Diseases of the Nose and Throat, by Dr. B. A. Waddington; Progress in Diseases of the Eye and Ear, by Dr. W. J. Atkinson, of Paterson; Progress in Bacteriology, by Dr. D. H. Bergey, of Philadelphia.

Wednesday Morning, 9 o'Clock.—What Measures are Practicable for Preventing the Spread of Tuberculosis? by Dr. Henry Mitchell, of Asbury Park; Arteriosclerosis and Nervous System, by Dr. Charles Lewis Allen, of Trenton; Neuralgia and Allied Affections, by Dr. William M. Leszynsky, of New York; Infant Feeding, some Difficulties in the Management of those Deprived of Milk, by Dr. Alexander McAllister, of Camden; Some Observations on the New Hæmostatic Adrenalin, by Dr. N. L. Wilson, of Elizabeth; A Plea for the Physician on the Witness Stand (discussion opened by Dr. William A. Davis, of Camden, and Dr. H. C. H. Herold, of Newark), by Dr. Daniel Stroock, of Camden; The Modern Treatment of Gonorrhœa and its Complications (discussion opened by Dr. E. B. Silvers, of Rahway, and Dr. Mortimer Lampson, of Jersey City), by Dr. Daniel Currie, of Englewood; The Treatment of Neurasthenia (discussion opened by Dr. Philip Marvel and Dr. G. H. Balleray, of Paterson), by Dr. W. B. Stewart, of Atlantic City.

Wednesday Afternoon, 3 o'Clock.—Some of the Infections, their Genesis, Habitat, Consequences, and Prevention (discussion opened by Dr. Ferdinand M. Jeffries, of New York, and Dr. W. L. Vroom, of Ridgewood), by Dr. Samuel E. Armstrong, of Rutherford; Diagnosis of Intestinal Perforation in Typhoid Fever (discussion opened by Dr. Alexander Marcy, of River-ton, and Dr. William H. Shippis, of Bordentown), by Dr. Joseph Stokes, of Moorestown.

The annual dinner will take place at the Hathaway Inn on Wednesday, at 7 P. M.

Another "Bellevue Hospital Scandal."—There has been another charge of cruelty to patients ending fatally made against the insane pavilion at Bellevue. It is alleged that a man who died recently had been seriously assaulted, and that the post-mortem examination made by the coroner's physician proved that the man had peritonitis, probably due to injury, and fractured ribs,

besides other marks of violence. Testimony was brought to show that these injuries were not on the man's person when he was admitted to hospital. Commissioner Keller thereupon instituted a searching inquiry which, he said, satisfied him that there had been no violence exercised on the patient at the hospital. He caused a second autopsy to be held, the findings of which were at direct variance with those of the coroner's physician. This second autopsy disclosed, it is stated, no evidence of peritonitis, and showed that the man's death was due to acute mania and exhaustion. It was further asserted that, as no evidence of hæmorrhage in the neighborhood of the fractured ribs was to be found, the fractures occurred after death.

Residents of the Bronx Ask for the Removal of a Hospital for Consumptives.—Residents of Spuyten Duyvil, Riverdale, and Kingsbridge, the Park District Protective League, and the Kingsbridge Improvement Association have made complaints to the municipal authorities that the patients of the Seton Consumptive Hospital do not keep within the grounds of the institution and are a menace to the health of the community. They want the hospital removed, especially as its location is near swampy ground and its death rate abnormally high. The hospital receives \$30,000 a year from the city for the care of poor consumptives.

Hospital Arrangements at the Pan-American Exposition.—Medical Director Roswell Park has concluded negotiations which have been going on for some time between the Exposition Company and the War Department at Washington, whereby the detachment of the United States Hospital Corps detailed at the Exposition will cooperate with the medical department of the Pan-American. This means that, no matter what great accident or catastrophe may take place on the grounds, there will be ample facilities for attending the injured immediately without calling upon city downtown hospitals for aid. Nearly one hundred men of the United States Hospital Corps are now encamped on the grounds, and it is proposed that this force be split up into several detachments with emergency hospital tents at various points about the grounds. The fact that the detail of 100 hospital corps men stands ready to act in any emergency will be a great assurance to nervous exposition goers. The hospital facilities at the Pan-American are now considered better and greater than those provided at any previous exposition, not excepting Chicago.

Dr. William H. Daly, whose suicide was recorded in our last issue, was well known and highly esteemed as a specialist in diseases of the nose and throat, having at one time been president of the American Laryngological Association and of the American Laryngological, Rhinological, and Otological Society, and chairman of the Section of Laryngology of the Ninth International Medical Congress. Dr. Daly served during the civil war as a medical cadet in various army hospitals and graduated from the Medical Department of the University of Michigan in 1866. He then engaged in practice at Pittsburgh, where he resided at the time of his death. He was a close personal friend of General Nelson A. Miles, and served on the staff of that officer as chief surgeon of volunteers during the Spanish war. Dr. Daly observed the character of the beef being issued to the troops and made a report to General Miles condemning it, which report served as a basis for the army beef scan-

dals. Dr. Daly had been quite despondent for some time, his wife having died about three years ago, and was apparently suffering from melancholia when he committed suicide.

Births, Marriages, and Deaths.

Married.

DOTY—REES.—In New York, on Wednesday, June 12th, Dr. Alvah H. Doty and Miss Blanche Ida Rees.

DWIGHT—RUNDLE.—In New York, on Wednesday, June 12th, Dr. Jonathan Dwight, Jr., and Miss Georgina Gertrude Rundle.

GARROTT—ADAMS.—In Sharpsburg, Maryland, on Wednesday, June 12th, Dr. E. W. Garrott, of Hagerstown, Maryland, and Miss Mary Kretzer Adams.

HART—ROBBINS.—In New York, on Wednesday, June 12th, Dr. Theodore Stuart Hart and Miss Mary Ayres Robbins.

HEISKELL—BRYAN.—In Philadelphia, on Tuesday, June 11th, Dr. Sidney Heiskell, of Baltimore, and Dr. Doralyn Bryan.

HICKS—THAYER.—In East Rockaway, N. Y., on Wednesday, June 5th, Dr. Shirley Hicks and Miss Minnie Thayer.

JAMAR—SAVAGE.—In Reading, Pennsylvania, on Wednesday, June 12th, Mr. J. H. R. Jamar, son of Dr. John H. Jamar, of Elkton, Maryland, and Miss Isabelle R. Savage.

JOHNSTON—DRAKE.—In Detroit, on Wednesday, June 12th, Lieutenant Edward Neele Johnston, Corps of Engineers, and Miss Cornelia Bissell Drake, daughter of Dr. Harlow B. Drake.

JONES—JOHNSTON.—In Washington, on Thursday, June 13th, Dr. James T. Jones and Miss Minnie Frances Johnston.

MACKEAN—FLAGLER.—In Washington, on Wednesday, June 12th, Dr. George W. MacKean, of Nova Scotia, and Miss Elizabeth Moore Flagler.

MAGRUDER—GULICK.—In Baltimore, on Friday, June 14th, Dr. Alexander F. Magruder, United States Navy, and Mrs. Ida Newton Gulick.

RANDLE—FLEMING.—In St. Louis, on Thursday, June 6th, Dr. Henry T. Randle, of Clayton, Missouri, and Miss Josephine M. Fleming.

READING—RULOFSON.—In San Francisco, on Wednesday, June 5th, Dr. Wallace Wall Reading and Miss Clara Estelle Rulofson.

STOCK—SCHIEKLER.—In New York, on Wednesday, June 12th, Dr. Caspar Stock and Miss Lillian Schiekler.

WILCOX—MCLLWAIN.—In Washington, on Wednesday, June 4th, Dr. William Wilcox and Miss Annie Reade McIlwaine.

WILSON—WILSON.—In Washington, on Wednesday, June 12th, Dr. Arthur Lee Wilson, of Lynchburg, Virginia, and Miss Elinor Wilson.

Died.

BLOCH.—In Denver, on Monday, June 17th, Dr. A. J. Bloch, of New Orleans, in the thirty-fourth year of his age.

BIGGS.—In Rochester, on Friday, June 14th, Dr. William H. Briggs, in the seventy-ninth year of his age.

CALDWELL.—In Freeport, Illinois, on Friday, June 7th, Dr. William S. Caldwell, in the sixty-eighth year of his age.

CAMPBELL.—In Worcester, Massachusetts, on Friday, June 14th, Dr. W. J. Campbell.

CHILTON.—In Dallas, Texas, on Thursday, June 6th, Dr. R. H. Chilton, in the fiftieth year of his age.

ELLIOTT.—In New York, on Saturday, June 15th, William M. Elliott, youngest son of Dr. George A. Elliott.

FARRAR.—In Ridgeway, Pennsylvania, on Friday, June 14th, Dr. Percival J. Farrar.

GILLASPY.—In St. Louis, on Thursday, June 6th, Dr. Rufus Gillaspay, in the forty-third year of his age.

JOYCE.—In St. Louis, on Monday, June 10th, Dr. P. W. Joyce, in the thirtieth year of his age.

LEWIS.—In Kansas City, Missouri, on Saturday, June 8th, Dr. Eugene K. Lewis, in the forty-ninth year of his age.

MARTIN.—In Belgrade, Maine, on Sunday, June 16th, Dr. R. J. Martin, of Augusta, Maine.

SEEBOLD.—In Baltimore, on Wednesday, June 12th, Dr. Charles Scott Seebold, in the fifty-first year of his age.

SMITH.—In Lingletown, Pennsylvania, on Sunday, June 16th, Dr. William C. Smith, in the seventy-third year of his age.

TIMPANY.—In Toledo, Ohio, on Friday, June 7th, Dr. Robert H. Timpany, in the thirty-sixth year of his age.

Pith of Current Literature.

Journal of the American Medical Association, June 15, 1901.

The Natural Method of Teaching the Subject of Medicine. By Dr. William Osler.

Relation of the Medical Profession in the Twentieth Century to the Tuberculosis Problem. By Dr. S. A. Knopf.

Gumma of the Spermatic Cord, with Report of a Case. By Dr. R. R. Campbell.—This case is interesting chiefly on account of the rarity of syphilitic manifestations in this particular location.

Surgical Shock. By Dr. William H. German.

Non-constrictive Dressings for Fractures. By Dr. J. F. Pritchard.—Under no circumstances in the treatment of diseases and injuries should we interfere with the beneficent efforts of Nature, and the author points out that an unimpeded circulation will give a more rapid healing process than is attainable if, by a constrictive dressing, the circulation is impeded in the slightest degree. All indications are fulfilled if the broken fragments of bone are in apposition and at rest. In the old fracture-box this principle is partially applied, and the so-called Hodggen's splint gives for fractures of the leg and thigh a plan of suspension that meets all requirements. Plaster-of-Paris splints or casts should never under any circumstances be used for a primary dressing. Illustrative cases follow.

Acute Glaucoma Developing in a Cataractous Eye, after Cataract Extraction in other Eye. Iridectomy and Cure. By Dr. H.-N. Rafferty.

Sitophobia of Enteric Origin. By Dr. Max Einhorn.—The author writes of sitophobia, meaning fear of food, a condition which may last a long period of time, and, if not successfully treated, may endanger life.

The Relation Existing between Diseases of the Conjunctiva, Nose, and Throat. By Dr. Heman H. Brown.—The author points out the need there is that the ophthalmologist should bear in mind the fact that in the treatment of conjunctivitis he is not dealing with an isolated tissue.

Round Ligament Ventrosuspension of the Uterus. By Dr. D. Tod Gilliam.—The method of suspension indicated in the title is believed by the author to be the nearest approach to the ideal, and to be superior to all other methods, both from a physiological and a utilitarian standpoint.

Magnetic Foreign Bodies in the Eye. By Dr. E. Villiers Appleby.

Variability of the Tubercle Bacillus. By Dr. Carl Ramus.—The author's conclusions are that: (1) The tubercle bacilli are not always so easy to demonstrate as is commonly believed; (2) the fuchsine solutions, like those of other dyes, cannot at all times be absolutely depended upon; (3) tubercle bacilli from different patients, and from the same patient at different times, will not invariably stain by one method; (4) the staining variations probably depend on physical and chemical changes in the bacterial substance, instituted either by antitoxic action, by the products of associated organisms, or by a combination of both; (6) in the absence of demonstrable tubercle bacilli, where physical signs of tuberculosis exist, a prompt diagnosis of that disease should be confidently made in the interest of the patient,

and no valuable time be lost in waiting for typical bacilli to appear.

Medical Colleges and Professional Standards. By Dr. Inez C. Philbrick.—The need of fewer and better institutions is pointed out.

Philippine Customs and Habits. By Dr. J. C. Minor.

Medical Departments in Public Libraries. By Dr. C. D. Spivak.

Medical News, June 15, 1901.

Decortication of the Lung for Chronic Empyema. By Dr. George Ryerson Fowler.—The author believes that: (1) Decortication of the lung is an operation adapted to all cases of old empyema in which extensive tuberculous lesions of the lungs, discoverable prior to operation, are not present, and in which the patient's condition will permit of a major operation; (2) it may be advantageously substituted for Estlander's operation in the majority of instances in which the latter has been considered, up to the present time, as being indicated; since it is a more rational procedure, in that it combines the advantages of restoration of function of the lung, so far as possible, with closure of the empyemic cavity; (3) it should replace Schede's operation in all cases; (4) the method by extirpation of the diseased portion of the pleural membrane, including the visceral, cortical, and diaphragmatic portions, is the operation of choice; (5) failing this, visceral pleurectomy should be selected; (6) pleurotomy, with simple detachment of the visceral layer of the diseased pleural membrane, gives sufficiently good results to warrant the surgeon in resorting to this procedure in cases in which the condition of the patient will not permit of the application of the other and more desirable methods; (7) whatever operative method is adopted, the most complete access possible to the cavity of the chest should be obtained, and rapid closure of the opening in the chest-wall afterward secured, since the complete reexpansion of the lung must depend largely upon the normal respiratory movement; (8) pulmonary or respiratory exercises should not be neglected in the after-treatment, since they aid greatly in the restoration of the function of the lung.

A Study of some Complications and Sequelæ of Typhoid Fever. By Dr. H. A. Hare and Dr. H. R. M. Landis.

The "Porro-Cæsarean Operation," with Report of Two Successful Cases. By Dr. James H. Glass.

The Treatment of Scarlatinal Nephritis. By Dr. Charles Gilmore Kerley.—A remedy which stands out prominently superior to all others, is the hot-water flushing of the colon, and the author looks upon the colon flushings as being of more value in restoring the kidney function than any other one measure. It may be used with advantage when the urine first becomes scanty, as well as when convulsions are threatened or present. For a child three years of age, from sixteen to twenty-four ounces of normal salt solution at 110° F. are introduced into the colon by means of a rectal tube, which should be inserted at least ten inches. This should be repeated every six or eight hours and will be retained by most patients. After from three to five flushings, in a stubborn case, the kidneys often begin to act, and soon there is a fairly free flow of urine.

Boston Medical and Surgical Journal, June 13, 1901.

Internal Medicine in the Nineteenth Century. By Dr. N. S. Davis, Jr.

Some Observations on Chronic Seminal Vesiculitis. By Dr. Arthur L. Chute and Dr. Richard F. O'Neil.—The experience of the authors leads them to believe that this disease is much more frequent than it has generally been supposed to be. Among five hundred and forty patients presenting various sorts of genito-urinary disease were found sixty cases of seminal vesiculitis. A point on which the authors would lay stress is that seminal vesiculitis, secondary to urethritis, is seldom a sharply defined single disease, but is practically always associated with more or less chronic prostatitis and chronic involvement of the posterior urethra. The treatment which has given the authors the best results is massage of the vesicles and ducts of the prostate as well. As the authors believe that a certain number of the cases of impotence, and many of sterility, are due to vesiculitis, its treatment thereby has a wider importance than the mere remedying of the discomfort the patients suffer. They advise the examination by the rectum of all patients with urethral disease in whom the disease is not progressing favorably, particularly of those showing the so-called neurasthenic symptoms.

Iodophilia. By Dr. Theodore Dunham.

Contributions from the Long Island College Hospital, Boston Harbor. Cystic Tumor of Median Nerve; Operation; Restoration of Function. By Dr. A. S. Hartwell.

Medical Record, June 15, 1901.

A Note on the Spread of Yellow Fever in Houses. Extrinsic Incubation. By Dr. H. R. Carter.—It is well known that when a case of yellow fever develops in a house, the house may become endowed with such properties that people susceptible to yellow fever may contract the disease by visiting or residing in the house. The author adduces evidence to show that a certain interval from the development of the infecting case of yellow fever passes before this property of communicating the disease to other people is attained by the place. This time agrees with the time that Dr. Reed finds to elapse from the infection of the mosquito by biting a yellow-fever patient to the time the mosquito becomes capable of communicating the disease to man. This time is placed definitely at not less than twelve days, and up to eighteen or more days.

On the Origin of Cancer: What Remains to be Demonstrated. By Dr. Samuel W. Bandler.

The Redundancy of the Preinsula in the Brains of Distinguished Educated Men. By Edward A. Spitzka.—In the highly intellectual, according to the author, the excessive growth and development of the left preinsula causes a displacement of the opercula, even though the latter be very well developed. In the defective, exposure of the preinsula is due to deficient development of the opercula. In such cases the insula itself is of inferior development, indicated by the soundings of the Sylvian cleft, by the flatness of configuration, and by the lesser area of the insular cortex.

Philadelphia Medical Journal, June 15, 1901.

The Topical Treatment of Focal and Jacksonian Epilepsy. By Dr. J. William White.—A method of treatment proposed by the author is described as follows: The affected centre being determined in advance, its relation to the cranium is indicated by a silver or iodine mark upon the scalp. The scalp is sterilized and

resterilized three times at intervals of twelve hours, not only before the trephining, but also before each subsequent application of the treatment. A horseshoe-shaped flap is raised and a half-inch button of bone removed with a small trephine. The dura is left intact. Thirty minims of a sterile two-per-cent. solution of eucaine are then injected into the brain substance at the centre of the trephine opening, the point of the needle being introduced about three quarters of an inch. The needle is gradually withdrawn as the last ten minims of the solution are injected. The flap is replaced. The patient is returned to bed and, on the day of operation and the following day, should receive full doses of bromides. At intervals, to be determined only by experience, the injection is repeated. The patient should be kept in bed at least four hours after each injection and should take bromides for from one to two days.

Theoretical and Practical Considerations on the Treatment of Jacksonian Epilepsy by Operation, with the Report of Five Cases. By Dr. James Jackson Putnam.

What I have Learned from One Hundred and Sixty-one Operations for the Relief of Senile Hypertrophy of the Prostate Gland. By Dr. S. Orville Horwitz.—The author's conclusions respecting prostatectomy are as follows: 1. With the exception of ligation of the internal iliac arteries, prostatectomy is the most dangerous of any operation that has been recommended for the relief of prostatic obstruction due to hypertrophy. 2. Suprapubic prostatectomy is the safest method, especially if combined with perineal drainage. 3. The best period to select for the performance of this operation is early, before the breakdown of catheter life and serious complications have supervened. 4. An atonied or a contracted bladder of long standing, associated with chronic cystitis, and attended by the formation of sacs, or pouches, contraindicates the operation. 5. A partial prostatectomy is indicated in those cases where a valve-like lobe exists and interferes with urination, or where there is partial hypertrophy of one of the lobes. 6. A complete prostatectomy is indicated where a hypertrophy of the three lobes has taken place, especially if the condition is associated with tumor formation projecting well back into the bladder, or has given rise to a stenosis of the prostatic urethra. 7. Perineal prostatectomy is best suited to those cases where the enlargement of the lateral lobes has a tendency to grow toward the rectum, or to obstruct the urethra. 8. When performing a perineal prostatectomy the semi-circular incision advocated by Pyle, or the transverse cut of Wolholm, is the most satisfactory. 9. The removal of a portion of a small, hard, fibrous prostate gland, by means of the perineal route, is a very difficult operation. There is danger of extirpating not only the entire gland, but the prostatic urethra as well. (*To be concluded.*)

The Value of the Combined Medical and Surgical Clinic to the Student. By Dr. Robert G. Le Conte.

A Case of Abdominal Pregnancy. By Augustus C. Behle.

Specialism and some of its Relations to the General Practice of Medicine. By Dr. Henry Wallace.

Lancet, June 8, 1901.

Some of the Anatomical Associations of the Kidneys from a Surgical Point of View. By E. Owen, F. R. C. S.—Will be abstracted at length in a later issue.

Retention of Urine. By C. Heath, F. R. C. S.—In this article the author reviews the various forms of retention of urine by the bladder. In children it is occasionally due to a tight foreskin; the treatment is simply to dilate the orifice with a forceps or by circumcision. Later in life, a child may have retention of urine from a calculus in the urethra, which calculus is usually lodged near the meatus and can be easily extracted. Occasionally retention in children is due to a thread having been tied around the penis, as children who have been punished for wetting the bed sometimes do in desperation. In the young adult retention is usually the result of gonorrhœa. It may be in the early, acute stage of the disease, or it may be in the later stage, when the inflammation has traveled up the urethra and affected the prostate. Another common form of retention in old gonorrhœa is the spasmodic variety, following the use of alcohol. Another and much more serious condition of retention is where the patient has had a stricture for years, which has been dilated several times. In all these forms the treatment consists in catheterization. With a certain amount of skill most cases of stricture should yield to the catheter, but it may be necessary to puncture and aspirate the bladder above the pubes.

Retention of urine sometimes results from atony of the bladder; the muscular coats of the bladder are so weakened by continual distention that they fail to contract. It is in these cases that retention with overflow and continual dribbling occurs, for which the physician should keep a sharp lookout. The treatment consists in frequent catheterization, the administration of strychnine and, if necessary, the use of electricity. In old age retention of urine is usually due to enlargement of the prostate gland. Here, again, the treatment is catheterization, followed, in suitable cases, by operation. The author prefers vasectomy to castration or prostatectomy.

Retention in the female occurs most generally in connection with pregnancy. A full bladder should never be overlooked, for many of the serious accidents following parturition are due to the prolonged presence of a full bladder. When in doubt catheterize. Lastly, there is that form of retention occurring in young people which is called "hysterical retention." In its treatment the great secret is not to pass a catheter. Put the girl into a hot bath and tell her to micturate; if she will not, suddenly pour cold water on her head, which will most certainly have the desired effect.

An Early Experience Concerning the Therapeutic Virtues of Iodide of Potassium in Asthmatic Affections. By Sir W. T. Gairdner.—The author describes how an old asthmatic patient of his, a minister, brought him many years ago a complicated prescription given him by Dr. Jephson, which had benefited his asthma greatly. The prescription contained fourteen or fifteen more or less active drugs, among them potassium iodide. By personal experimentation it was gradually determined that the beneficial effect was due to potassium iodide alone, since which time Dr. William Gairdner has steadily advocated its use in all bronchial affections.

Rat Plague. A Preliminary Communication on an Outbreak of Disease in Rats at Cape Town. By Dr. A. Edington.—The author has examined the bodies of rats supposed to have died of the plague at Cape Town, and finds that the micro-organism causing their death is not the bacillus of bubonic plague at all. The rat has a disease which is communicable to guinea-pigs, but not to rabbits, and to which rabbits are also refractory even after the disease has been passed through guinea-pigs.

Inoculation of the rabbit with the rat bacterium in its virulent form gives no protection against a subsequent inoculation with bubonic plague, thus proving that this rat plague cannot be bubonic plague. The morphological and cultural characteristics of the rat microbe are described and the results of inoculation experiments given.

Alcohol and Arsenic in the Ætiology of Alcoholic Neuritis. By E. F. Buzzard, M. B.—The author has carefully investigated 120 cases of alcoholic neuritis as well as some twenty other cases in which alcohol was a possible, but not a reliable, cause, with a view to determining the part played by alcohol in the causation of multiple neuritis. Special attention was paid to the following points, which are dwelt on at length: (1) age; (2) sex; (3) habits in reference to alcohol; (4) changes of a nutritional, vasomotor, or pigmentary nature in the skin, hairs, or nails; and (5), the result of treatment with arsenical drugs.

The author concludes that (1) alcoholic neuritis is more often found in the sequel of spirit drinking than in other forms of alcoholism; and (2) that clinical evidence is antagonistic to the idea that arsenic is the cause of alcoholic neuritis.

An Explanation of the Vulnerability of the Apices in Tuberculosis of the Lungs. By Dr. E. H. Colbeck and Dr. E. Pritchard.—The authors conclude that the vulnerability of the apices of the lungs to tuberculosis is largely determined by an alteration in the shape of the chest in conjunction with displacement and deficient musculature of the shoulder girdle. The importance of such alteration lies in the modification which these changes induce in the dynamical relations of the superior aperture of the thorax, whereby the movements of the apices become inverted in their relation to the normal respiratory rhythm. The exact position of the site of deposit is determined largely by the distance the apex rises above the border of the first rib. The practical bearing of this theory is the enormous importance of developing the muscles of the shoulder girdle with the object of "pulling the chest into shape." Any muscular movement bringing into play the great pectoral muscles should be sedulously carried out.

The Surgical Treatment of Ulcers of the Stomach which are or have been Complicated by Severe Hæmorrhage. By C. B. Keetley, F. R. C. S.

Vitality after Severe Injury. By W. H. C. Greene, M. R. C. S.—The author reports the case of a man who had fallen on some area railings and sustained the following injuries: Irregular wound in the left hypochondriac region, with fracture of the sixth, seventh, eighth, ninth, and tenth ribs; complete perforation of both walls of the stomach; perforation and laceration of the diaphragm; collapse of the left lung; and perforation of the pericardium and left ventricle of the heart. Yet the man lived for nine hours after receiving his injuries. Large rectal injections of saline solution undoubtedly helped to keep him alive.

The Morbid Anatomy and Origin of the Various Presystolic Murmurs Heard at the Apex. By Dr. C. C. Gibbes.—The presystolic murmur has been proved to be present under the following morbid conditions: 1. Obstruction of the mitral orifice by sclerosis and adhesions or by invagination of an auricular thrombus. 2. Simple dilatation of the mitral orifice. 3. Roughened margins of a normal-sized mitral orifice. 4. Insufficiency of the aortic valves, with (a) normal mitral orifice; (b) simple dilated mitral orifice; and (c) dilated mitral orifice with thickening of the cusps and chordæ.

The author holds that the presystolic murmur cannot arise entirely from the auriculosystolic blood current, as asserted by Gairdner. In all cases the two conditions common to the whole of them are: (1) Hypertrophy of the heart muscle and therefore increased muscle tones; and (2), loss of compensation, producing partial asynchronism, thereby causing the muscle tones to be heard during the diastolic period, the intensity of the presystolic murmur varying in proportion to the amount of hypertrophy present.

British Medical Journal, June 8, 1901.

Some of the Anatomical Associations of the Kidneys from a Surgical Point of View. By E. Owen, F. R. C. S.—(See note in abstract of *Lancet* for June 8th.)

Remarks on Skiagraphy and Fractures, Especially in their Medico-legal Relations. By C. H. Golding-Bird, M. B.—As an aid to diagnosis none will now question the value of the x rays; and while their employment is quite unnecessary in by far the larger proportion of cases, yet there is a certain class of doubtful cases where the use of skiagraphy is most advisable. Such doubtful cases are of two kinds: (a) Where, although it is certain that a fracture exists, there is yet doubt as to its exact location; and (b), where the very existence of fracture is doubtful. In all cases in which the nature of the accident leads to the possibility of any fracture which cannot with certainty be diagnosed, the surgeon should in self-defense give the patient the chance of skiagraphy to try and settle the point, though no practical outcome may result. For if he does not do this, the patient may have a skiagraph taken on his own initiative, and much trouble result thereby. Though over-reliance on mechanical aid to diagnosis, such as that of the x rays, in fractures may not be so detrimental to the patient, as when an exploratory operation is involved, yet it is only as a subsidiary agent to diagnosis that skiagraphy should be employed, and, even in this secondary capacity, its evidence in cases of difficulty and doubt should be received with caution, and only after due interpretation by some one whose experience warrants his speaking with authority.

The x rays are sometimes used to judge of the results of treatment of fractures, but those who are versed in the vagaries of the x rays will hardly care to stand or fall solely by such a test. In the majority of indirect fractures, even after the best of "setting" and treatment, the skiagraphs show an apparent maladaptation of the bones which, taken alone, would seem to indicate hopeless failure; yet the patients recover with perfectly sound and functional limbs. In order to satisfy the æsthetic requirements of skiagraphy, it would be necessary to operate upon almost every case, and that the bones should be adapted by screws or wires. If the final appeal is to be the beauty of the bone scar and not the utility of the limb, then every case must be so treated.

The following are some of the mistakes that have been and may be made by others than experts: A. *Can a skiagraph show a fracture where none exists?* 1. Epiphyseal lines have been mistaken for fractures. 2. Impacted fracture of the neck of the thigh can be simulated by a foreshortened view. 3. Fracture through the base of the olecranon is simulated always where the light is directly over the bend of the elbow; the rays penetrate the joint. 4. The acromioclavicular joint resembles a fracture. 5. The appearance of a gradual thickening of bone can be produced at will.

B. *Is it possible to miss seeing a fracture?* Yes,

though rarely. 1. Irregularity of bone outline may be completely masked, yet the line of light through the fracture is usually seen, no matter how closely the bones are adapted. 2. Fractures may be overlooked in the ribs and in the spine. 3. The centres of ossification in the ends of very young bones may be mistaken for detached bone or *vice versa*. 4. Where the bones are deep and much blood is extravasated, the image may be indistinct (base of the skull, etc.).

C. *Is it possible to show a fracture as still existing, though long united?* Yes. Early callus does not show, and the line of union will seem to be one of separation still.

D. *Can distortion be produced?* Yes, in several ways: 1. By foreshortening; also from the fact that x rays are divergent. 2. The appearance of gradual expansion of a bone can be easily produced by want of parallelism between the plate and the limb.

The article is accompanied by a special plate of most excellent skiagraphs, illustrating the various points mentioned above.

A Case of Oblique Fracture of Tibia and Fibula with Skiagraphs Showing Repair. By Dr. B. Duke.—The author reports a case of fracture of the tibia and fibula in which, although apparently perfect recovery had taken place, the skiagraph taken on the eightieth day after injury showed wide separation between the ends of the fractured bones. But a second skiagraph, taken eighteen months later, showed recovery to be perfect.

A Case of Cervical Rib; Obliteration of the Arteries of the Right Arm; Gangrene of a Portion of Several Fingers; Excision of the Rib. By T. E. Gordon, M. B.—The author reports a case of cervical rib occurring in a man aged thirty-two years, causing obliteration of the arteries of the right arm and gangrene of the fingers. A skiagraph showed the presence of a cervical rib on both sides. The author reviews the literature of the subject and epitomizes his remarks as follows: 1. The cervical rib was in some way the cause of the arterial obliteration. 2. The circulation through the subclavian was not obstructed. 3. The occurrence of embolism may be excluded. 4. The manner of the obliteration suggest thrombosis, which in turn implies preceding disease of the endothelium. 5. The cause of this arterial disease was very probably in part, but only in part, the carrying of heavy weights. 6. If the rib acted directly on the artery, our present knowledge of pathology cannot explain it. 7. The rib may have acted on the artery indirectly through the nerves. 8. The nerves are more likely to have suffered than the artery, and nervous symptoms are much more common than arterial. 9. A nerve lesion is capable of causing gangrene. 10. A nerve lesion may cause structural lesions in the vessels. 11. The absence of clear signs of a peripheral neuritis is a striking argument against the theory of nerve origin. 12. The case resembles one of Raynaud's disease. 13. But in Raynaud's disease the arteries are stated to be healthy. 14. Structural changes in arteries may arise not only from nerve lesions generally, but from disease of vasomotor nerves in particular. 15. In cases of cervical rib the occasionally occur symptoms which may possibly be explained by injury to the cervical sympathetic. 16. A study of the anatomy of the region concerned suggests that the rib may have excited its evil effects not at its distal but at its proximal extremity; here the rib is in intimate relation not only of the seventh and eighth cervical and first dorsal nerves, but also of the inferior cervical sympathetic ganglion and its branches.

The Effect of the Röntgen Rays in a Case of Chronic Carcinoma of the Breast. By A. Clark, F. R. C. S.—The author reports the case of a woman, aged sixty years, suffering from chronic carcinoma of the breast, in which the use of the Röntgen rays over a period of nine weeks was followed by marked improvement. Islands of epithelium appeared over the diminished ulcerated surface, and the indurated lump decreased in size. The glands in the axilla grew smaller, there was less pain, and the general condition of the patient improved greatly.

Note on the Pathology of Toxic Amblyopias. By J. H. Parsons, F. R. C. S.—The author has studied the effect of the local action of nicotine upon the superior cervical ganglia of cats, and concludes that the action of nicotine may be supposed to be twofold: (1) Vascular, causing vasoconstriction of the arterioles; (2) paralytic, upon the synapses either of the cone fibres, or of the inner granules, or of both.

Paralysis of the Cervical Sympathetic. By Dr. P. Stewart.—The author reports a case of lesion of the cervical sympathetic which is unique, not so much because it exemplifies to a marked degree nearly all the classical symptoms of the cervical sympathetic, but because it demonstrates with great clearness the precise limits of one symptom in particular—*anidrosis*. This has not been previously recorded. It is sharply limited by the middle line, it extends as low as the third rib in front and the third dorsal spine behind, and it includes the whole upper extremity on the affected side.

Wiener klinische Rundschau, May 19, 1901.

Bronze Diabetes.—Professor August Murri reports the case of a woman, fifty-nine years of age, who had suffered from diabetes for many years and who developed a bronze coloring of the skin. After a long stay at the hospital, the sugar disappeared from the urine, and the skin and mucous membranes assumed their normal white color. Albumin, peptone, acetone, or hæmoglobin were never found in the urine. (*To be continued.*)

Hospital Gangrene.—Dr. A. Brabec reports a case of this very rare condition appearing in Maydl's clinic in Prague. It was in a young girl, who had an ulcer on the external malleolus. During its treatment at the clinic, gangrene appeared. Bacilli and cocci were found in the secretion, but no organism which could be held to specific account. (*To be concluded.*)

Acute Trigger Finger with Periosteitis. By Dr. E. von Czyhlarz.

Klinisch-therapeutische Wochenschrift, May 19, 1901.

Medical Treatment of Perityphlitis. By M. Bourget. (*Continued article.*)

Effect of Steam Baths upon the Skin of the Face.—Dr. Rudolf Steiner has devised an apparatus for playing steam, plain or medicated, upon any desired part of the face. He has had good results from this treatment in cases of seborrhœa oleosa and acne vulgaris.

Centralblatt für Gynäkologie, May 11, 1901.

Pathogenesis of Eclampsia.—Dr. Arthur Dienst has investigated this subject for a year and a half in Küstner's clinic. He finds that both mother and child are involved in an eclamptic seizure. The blood serum and the urine of both are similarly pathological, as are the changes in the internal organs. In the blood, the fibrin-forming elements are increased; in the urine, albumin, casts, and blood are found. The essential cause of

eclampsia, he thinks, resides in the insufficient elimination of toxic substances by the liver and kidneys of the mother. This depends upon insufficiency of the mother's heart or kidneys, or upon anomalies of these organs. The metabolic results of foetal life, added to those of the mother, normally increased during pregnancy, are the elements which provoke the changes in the maternal blood. If these do not lead to eclamptic seizures, but to a toxæmia, we may have eclampsia without albuminuria and with sound kidneys; but if there is a gradual heaping up of the poisons, eclampsia with albuminuria appears suddenly. *Postpartum* eclampsia is due to the impairment of the hepatic function, deranged by the same toxins as those which affect the kidney.

Cæsarean Section after Vaginal Fixation.—Dr. Hermann Pape reports eight cases from the literature and one of his own, in which Cæsarean section at term was necessary after the uterus had been strongly fixed in ante-flexion by the vaginal method.

Dialyzed Ergot. By Dr. E. Niebergall.

A New Abdominal Binder. By Dr. Kurt Witthauer.

May 18, 1901.

Conservative Treatment of Inflammatory Disease of the Adnexa.—Dr. H. Thomson believes in the vaginal incision of a pyosalpinx. The hæmorrhage is never severe and can always be controlled by tamponing or ligature or by forceps. The posterior fornix should always be the one opened, the incision should be a free one, and the pus cavity should be thoroughly opened and drained as other abscesses are. Recovery is prompt, as a rule; pain and the tumor disappear, and if the result is not satisfactory, a radical operation may still be performed.

Ætiology of Facial Paralysis after Spontaneous Birth.—Dr. E. Frank reports such a case as a rarity, and finds the explanation in the severe pressure of the left shoulder against the aural region.

Drainage after Laparotomy.—Dr. L. Seeligmann recommends drainage through the pouch of Douglas with closure of the abdominal wall, in laparotomies which are complicated by adhesions or by soiling of the peritonæum. He cites an illustrative case.

Wiener klinische Wochenschrift, May 16, 1901.

Influence of Alcohol upon the Course of the Infectious Diseases.—Professor Max Gruber decries the routine employment of alcohol in the acute infections as being productive of more harm than good. He believes that it weakens the resisting power of the organism, but is sometimes useful in the collapse of some of the infectious diseases.

Ætiology of Acute Articular Rheumatism.—Dr. Gustav Singer takes issue with Wassermann and Meyer as to their recently described organism, and says that it is a variety of the *Streptococcus pyogenes*. The specific organism has not yet been isolated, he thinks.

Clinical Diagnosis of Renal Infarcts. By Dr. Rudolf Schmidt (*concluded*).—The author says that it is always desirable, in cases of renal colic, to try to distinguish between intrarenal and extrarenal lesions (ureteral). Intrarenal lesions are more sharply circumscribed in the neighborhood of the kidney; if there is an infarct, the kidney itself is sensitive to pressure, the pain is continuous, albuminuria suddenly appears, or the sediment shows nephritic changes. Ureteral lesions have a tendency to radiate, the course of the ureter is sensitive, hydronephrosis may appear, and the pain is intermittent. A

high-tension pulse speaks against an infarct, but pain appearing while in the recumbent position is characteristic. Hæmaturia is rarely seen in infarction, but a rapidly appearing and rapidly vanishing intense albuminuria is seen in such cases. Renal infarction, complicated by enteroptosis, offers an unfavorable prognosis. Lying on the healthy side increases the pain of a kidney the seat of an infarct. It may happen that total occlusion of the renal artery will give no urinary symptoms. Oliguria or anuria may be seen in bilateral infarction, but there is no vesical tenesmus.

May 23, 1901.

Theodore Meynert.—A memorial address on the unveiling of Meynert's monument, by Professor Anton.

Alimentary Glycosuria.—Dr. Emil Raimann says that the assimilation of sugar is an expression of the general healthy condition. It is influenced by a variety of external and endogenous toxins.

Juvenile Form of Progressive Paralysis.—Dr. Josef A. Hirschl points out the essential differences between the progressive paralysis of adults and that of the youthful. Congenital syphilis may be the cause of the disease in the latter, and it begins in early life. Hereditarily tainted individuals are subject to it. The prodromal stage is long and rich in symptoms. At the height of the disease simple dementia is most commonly seen rather than paralytic mania or hypochondriasis; remissions are uncommon. The disease lasts a comparatively long time. The post-mortem findings are those of cerebral sclerosis with a marked leptomeningitis.

Münchener medicinische Wochenschrift, May 14, 1901.

Mixed Ether and Chloroform Narcosis.—Dr. H. Braun describes an apparatus of his own devising for the combined administration of ether and chloroform, which he characterizes as safe, cheap, and as employing the principal elements of the two drugs with a minimum of chloroform.

Acute Yellow Atrophy of the Liver. By Dr. Aby Bey Ibrahim (*continued article*).

A Case of Noma in Old Age. By Dr. O. Zuseh.

Diphtheria Antitoxine Results, 1894-1900.—Dr. F. Cuno writes that the results from the use of the diphtheria antitoxine in Dr. Christ's hospital have been excellent, showing a remarkable decrease in mortality when compared with the years preceding its introduction. Intubation has worked better in their hands than tracheotomy.

Contusions of the Pelvis. By Dr. F. Bähr.

A Case of Inguinal Ovarian Hernia. By Dr. Quadflieg.

Virulence of Scarlatinal Contagion.—Dr. Friedrich Schmidt relates a case in which a puerperal woman became infected from the bedding of her husband, who had had scarlatina three months previously. He emphasizes the necessity of scrupulous disinfection after this disease.

Kissingen Saal-baths in Heart Disease. By Dr. Leusser (*conclusion*).

Indépendance médicale, May 29, 1901.

Recurrent Hemichorea.—M. Paul Farez reports the case of a young woman, nineteen years of age, who, after three months, had a recurrent attack of hemichorea. She was completely cured by a single hypnotic *séance*, by means of suggestion.

Discipline of Tuberculous Subjects.—M. Portes emphasizes the necessity of strict discipline among persons

suffering from pulmonary tuberculosis, this discipline to consist in teaching them, in sanatoria, if necessary, the hygienic measures essential to prevent the spread of the disease.

Lyon médical, May 26, 1901.

Gaseous Cysts of the Intestine.—M. Jaboulay speaks of microbic invasions of the intestine, slow in their course and development, which tend to produce large collections of gas. If these are not controlled, peritonitis and occlusion of the intestine may follow. He relates a case in a man, fifty years of age, who, from this cause, had a pyloric stenosis which necessitated operation.

Case of Pemphigus Vegetans. By M. Paul Jourdanet.

Parkinson's Disease. By M. Pierre Grange.

Gazette hebdomadaire de médecine et de chirurgie, May 12 and 16, 1901.

Intestinal Occlusion Following Appendicitis. By M. Broca.—A clinical lecture.

Preparation of Patients for Surgical Operations.—M. L. Dor shows by experiment that iodides administered before operations on dogs limit the virulence of experimental sepsis. Despite the disadvantages of the iodides, he thinks the principle might be employed with human beings.

Province médicale, May 18, 1901.

Nervous Arthropathy. By M. Durand.

Ancient Man in the Rhone Basin. By M. Mayet.

Hæmoptysis of Non-tuberculous Character.—M. J. Charvet says there are certain anomalous forms of pneumonia which give rise to hæmoptysis. Sometimes a previous attack of grippe predisposes to this condition. It may arise in a patient suffering from pneumonia alone, or from pneumonia complicated by an infarct, or from pneumonia in the course of tuberculosis or following an old pleurisy. (*To be continued.*)

Presse médicale, May 18, 1901.

Circular and Lateral Suture of Veins.—M. G. Clermont gives an exhaustive review of the entire subject of venous suture. He recommends both the circular suture and the lateral suture, the latter with a round needle and fine silk; an additional suture into the neighboring tissues close to the vein is advisable. The union of the venous walls need not be close. If, on central pressure, hæmostasis remains perfect, the result will be good. [The article is full of detail and is of interest to surgeons.]

Eruptions Due to Orthoform.—M. W. Dubreuilh reports a number of cases of eruptions following the local use of orthoform. He describes them under two main divisions: (1) Erythematous eruptions, complicated or uncomplicated by vesiculation and pustulation; (2) the rarer form of gangrene of the local area in which the drug is used.

Progrès médical, May 25, 1901.

Rhinopharyngeal Origin of Goitre.—M. Hamon du Fougerey finds an explanation for the origin of goitre in lesions of the nose and pharynx. Vascular lesions of the oropharynx produce simple goitre; of the pharynx and nose, exophthalmos; of the mucous membranes of the nose and pharynx, goitre and exophthalmos. Vascular and sympathetic disturbances of the oropharynx evoke goitre and cardiac troubles; of the pharynx and nose,

exophthalmos and cardiac disturbances; of the entire rhinopharynx, the classical picture of Basedow's disease. Sympathetic disturbances alone of the rhinopharynx call forth heart affections with neither goitre nor exophthalmos. Treatment of the nose and the pharynx is to be directed against these lesions.

Riforma medica, April 27, 29, and 30, and May 2, 1901.

On some Symptoms of Primary Cancer of the Head of the Pancreas. By Dr. Ferruccio Schupper.—The author reports the histories of eight cases of cancer of the head of the pancreas, and sums up the symptoms observed as follows: The disease was more prevalent in males, and the age varied from thirty-three to seventy years. Alcoholism seemed to favor its development, but there was no hereditary history of cancer in the cases observed. The subjective symptoms were, at first, slight, so that the patients presented themselves only when the disease had made considerable progress. This is a useful differential sign in the diagnosis of cancer of the pancreas from cancer of the stomach. The liver was enlarged in four cases. In one case there was a rapid diminution in its size within four days. The gall-bladder was swollen and painful on palpation. Jaundice developed suddenly in one case. In two cases it came on a few days after a severe pain was felt in the epigastrium; in the remaining cases it appeared gradually. In most of the cases the tumor was palpable, and in some it moved with respiration owing to adhesions or secondary invasion of the stomach. A profound and rapid cachexia accompanied all the cases. The supraclavicular glands were involved in only two cases, the inguinal more frequently. In two cases the pain was severe and resembled colic, but in the others it was moderate. In two cases there was subnormal temperature toward the end of the disease, while in three there was fever, depending on infection of the biliary tract or on peritonitis. Moderate degrees of gastrectasia were observed in two cases, and there were, in addition, vomiting of food and of coffee-brown material, and diarrhoea preceding the icterus. In three cases there was a splenic tumor, and in one case marked salivation. In two alcoholics with infections of the biliary passages there was albuminuria late in the disease. Glycosuria and polyuria were observed in one out of eight cases, and even in this one the signs disappeared rapidly. When present, glycosuria is a valuable diagnostic sign, but when absent it is of no negative value.

May 3, 4, and 6, 1901.

A Comparison of Hæmolytic and Agglutinating Action in Life and in Vitro. By Dr. Alessandro Bongiovanni.—There are marked differences between the hæmolytic and agglutinating powers of serum *in vivo* and serum *in vitro*. After being removed from the body the red blood cell alters its sensibility to the influence of agglutinating and hæmolytic agents. These red cells, according to the author's experiments, acquire a greater resistance toward the coagulating and destructive agents, though the extraction and defibrination of the blood are manœuvres which should weaken the organic elements, according to the generally accepted notion. The other cells of the blood in the rabbit are especially sensitive to the hæmolytic powers of the bile of the ox and to the agglutinating powers of the serum of the sheep. They are less sensitive to the serum of the frog. In the body, however, the serum of the frog is more active than the other agents before mentioned.

May 7, 1901.

On the Capsule of Bacteria. By Dr. Icilio Boni.—The author recommends the following method of staining for capsular organisms: (1) The specimen is placed in a drop of a liquid composed of a white-of-egg beaten with fifty cubic centimetres of glycerin and two drops of formaldehyde and filtered; (2) it is fixed on a slide over the flame until all the glycerin has evaporated; (3) stained in Ziehl's solution for from twenty to thirty seconds; (4) washed in water and dried; (5) contrast-stained in Loeffler's solution for from four to five minutes; (6) washed in water, dried, and examined in Canada balsam. By this method the author has been able to obtain well-stained capsules in a number of species of bacteria, including the *Bacterium coli commune*, the bacilli of glanders, diphtheria, typhoid fever, etc. The author is investigating the significance of the capsule in bacteria, and his work, thus far, has shown that the capsule is the product of the bactericidal action of antiseptics or of antibacterial substances in or out of the body. The peripheral layers of the bacterial cell are injured and become swollen, so that their staining qualities are altered. This explains why sometimes a germ is found encapsulated and sometimes not. On the other hand, this theory destroys the morphologic value of the capsule.

A Contribution to the Treatment of Anthrax. By Dr. Salvatore Gugliuzzo.—The author reports eight cases of anthrax and concludes as follows as regards the treatment of this affection: (1) That in man the most common manifestation of anthrax is the malignant pustule, which may originate from infection through a very slight abrasion, or from the use of meat of animals that have died from anthrax; (2) in the treatment of this disease the most efficient means are deep cauterization with the Paquelin cautery, the use of Selavo's serum, injections of phenol, or of sublimate. By these means the results of treatment are so good that fatal terminations are almost the exceptions. Seven of his eight patients recovered.

May 8, 1901.

Notes on Five Cholecystotomies for Biliary Calculi. By Dr. Tito Scarrone.—The author's conclusions are as follows: (1) Cholecystotomy in one operation is to be preferred to cholecystotomy in two stages; (2) when the bile-duct is pervious, it is preferable, after suturing the wound in the gall-bladder, to make the line of sutures extraperitoneal; (3) cholecystotomy is to be preferred to cholecystectomy.

Vratch, April 21 (May 3, N. S.), 1901.

On Sporadic Elephantiasis. By Dr. L. V. Orloff.—The author reports four cases of elephantiasis in which he performed operations that included the removal of the growth and the restoration of the parts involved. (*To be continued.*)

Haffkine's Lymph, and other Remedies against the Plague, which Produce Active Immunity. By Dr. A. F. Vigur.—As the result of his experiments, Vigur concludes as follows concerning Haffkine's lymph: 1. Monkeys of the species *Macacus radiatus* can tolerate Haffkine's lymph injected subcutaneously. 2. These monkeys do not show any local or any general reaction after the injection of six times the amount of serum usually injected into human beings. 3. In order to obtain a general reaction in these monkeys, very large quantities of the serum must be injected, and in order to produce a

marked local reaction a large quantity of Haffkine's serum must be injected at some tender spot in the skin of the animal. 4. Even the injection of the sediment from 135 cubic centimetres of the serum is borne well by the monkeys. 5. These animals, after injection with Haffkine's lymph, present a certain degree of immunity against the infection, while some of them are fully immune. The test for the quantity of lymph required is always the reaction. 6. Monkeys that have shown a reaction present a considerable mortality after two months and perhaps earlier. 7. In cases where infectious material has got into the serum, abscesses very rarely occur either in man or in animal. 8. The liquid part of Haffkine's lymph has but little effect. As a rule, from forty to sixty cubic centimetres were required to produce a reaction in *Macacus rhadiatus*. (*To be continued.*)

On the Question of Ankylosis of the Spine. By Dr. A. N. Vinokoureff.—The author describes two cases of ankylosis of the spine that he observed while the process was developing. In the first of these cases the "ankylosis" was due to inflammation of the spinal meninges. Thus it belonged to the type of cases described by Bechthereff, who spoke of the connection between disease of the spinal meninges and ankylosis of the spinal column. In the present case the paresis, the muscular atrophy, and the disturbances in sensation were not in the upper part of the body, as Bechthereff describes, but in the lower; and there was no kyphosis. In the second case there was also an acute inflammation of the spinal meninges followed by a chronic meningitis and by ankylosis of the spine. In this case, however, the disease had remained in the stage of irritation, and had not gone on to the paralytic stage as in the first case. As the result of his observations the author concludes as follows: "Ankylosis of the spine" is a symptom of spinal meningitis. The location and extent of the ankylosis depends upon the location and extent of the meningeal inflammation. The statement of Bechthereff, that the symptoms first appear at the upper part of the body and then travel downward, is not founded on facts. The parietic condition and the muscular atrophy may be absent. Kyphosis may only appear late in the disease, and the same is true of the anæsthesia. He does not agree with Bechthereff in calling ankylosis of the spine the result of compression of the intervertebral cartilages by the distorted spinal column. Immobility of the spine as a symptom occurs in a number of conditions.

On the Question as to the Effects of High-tension Electric Currents upon the Human Body. By Dr. S. A. Broustein.—The author reports a case in which the accidental exposure to a strong electric current was followed by the development of a neurasthenic condition with symptoms of hysteria. It may be regarded as a traumatic neurosis. In these cases there may be a medico-legal question of malingering, but in the author's case this was excluded from the circumstances of the patient.

Kumyss Treatment and some Kumyss Settlements in Ufa. By Dr. P. V. Zesarievsky.

Chirurgia, March, 1901.

On the Treatment of Diffuse Suppurative Peritonitis by Laparotomy. By Dr. S. P. Fedoroff.—Laparotomy is at the present time the only method by which the life of a patient with general septic peritonitis may occasionally be saved. It must be performed so soon as the diagnosis is made. The use of antitoxic serum and the in-

jection of large quantities of salt solution may be of value as adjuvants. The laparotomy must be followed by the use of a copious irrigation of the cavity with some indifferent fluid at 40° or 50° C. The exposure of large loops of intestine is to be avoided as much as possible. The author recommends a method of draining the peritoneal cavity which is adapted to various topographic conditions of the peritoneal infection. For thorough drainage of the cavity he recommends three incisions in the abdominal wall—one median incision, or the operation wound proper, and two lateral incisions, parallel to Poupart's ligament on either side. Through these it will be possible to drain every part of the peritoneum where pus is apt to collect. If, at the time of the operation, pus is discovered in the omental bursa, it may be drained through the foramen of Winslow into the right lateral wound, or through an opening in the gastrocolic ligament. The author favors the wick drain suggested by Delagénière, consisting of a metallic tube perforated in ten places at one of its ends. Into this tube strips of gauze or of cotton yarn are drawn and the perforated end is introduced into the cavity.

On Operative Interference in Fibromyomas of the Uterus during Pregnancy. By Dr. Th. A. Alexandroff.—The author has collected statistics of twelve cases of fibromas in pregnant women, which were allowed to go on without surgical interference; of sixty-two cases in which enucleation or myomectomy was performed; of fifty-six cases of supravaginal hysterectomy; of thirty-three cases of complete hysterectomy, and of twenty-eight cases of Porro's operation. His conclusions on the moot question as to the operation of choice in these cases are as follows: The mere presence of fibromyoma in a pregnant woman does not constitute an indication for an operative procedure. Indications for the latter are symptoms threatening the life of the patient or the course of the pregnancy. In the absence of such symptoms the pregnancy must be allowed to take its course. Artificial labor and abortion must be excluded from the list of operations indicated in these conditions. Myotomy and enucleation are better performed in the first half of pregnancy. The immobility of the womb in the first half of pregnancy should be considered as an indication for enucleation or myotomy. Porro's operation is indicated only in multiple intramural fibromyomas. A conservative Cæsarean section with enucleation of the growths should be performed if the growths threaten to interfere with the progress of labor while the child is being born. If the patient's condition is poor, one may leave enucleation for a secondary operation.

On Excision of the Lower Extremity at the Hip-joint in Tumors of the Femur. The Best Methods of Operation and the Best Therapeutic Results. By Dr. B. G. Prgevalsky.—The author has collected 180 cases of operations on the hip-joint and analyzes them in detail. The following conclusions are the results of his study. The lowest percentage of mortality was obtained with Wyeth's method, namely, 12.8 per cent. Veitch's method does not give so low a mortality and is less easy of execution. There are not sufficient data to determine the value of Ravaton's operation, but it must be supposed that it is less dangerous than that of Veitch. The combination of Ravaton's and Veitch's methods can be justified neither from a scientific point of view nor for clinical reasons. Shock is the most frequent cause of early death in these operations. Cases of recovery from sarcoma of the femur after operation are so rare because the diagnosis is in most cases made too late.

Proceedings of Societies.

AMERICAN MEDICAL ASSOCIATION.

Fifty-second Annual Meeting, Held in St. Paul, on Tuesday, Wednesday, Thursday, and Friday, June 4, 5, 6, and 7, 1901.

The President, Dr. CHARLES A. L. REED, of Ohio, in the Chair.

General Session.

(Concluded from page 1058.)

The Control of Vice in the Army.—By the courtesy of the association, a delegation of the Women's Suffrage Society, which has been in session in St. Paul, was allowed ten minutes in which to present a memorial upon the subject of the regulation of vice in the army. Miss Susan B. Anthony, the first speaker, said that she wished to protest, on behalf of their organization, against the policy of controlling vice in Manila, Hawaii, and Puerto Rico. She hoped that some action would be taken in regard to this question by the American Medical Association, which would no doubt have great weight in influencing legislation.

Miss Anthony was followed by the Rev. Anna Shaw, who declared that the time had come when we should not be content with attempting to regulate vice, but should begin to protect virtue.

Dr. Louis L. Seaman, of New York, who at the previous session of the association had introduced a petition in favor of reestablishing the army canteen, said that the surgeons of the army were just as anxious as the members of the Women's Suffrage Society to protect the virtue of the soldiers. Vital statistics of the army in Peking showed that fifty per cent. of the patients treated there were affected with venereal disease, and that since the abolition of the army canteen the number of these diseases had almost doubled. He said the army canteen had been opposed by misguided enthusiasts, who should stop interfering with matters in the army, which they did not understand.

President Reed cut off further discussion upon the subject by stating that the meeting would proceed with its regular order of business.

State and County Societies.—Dr. McCormack presented the following resolution, which was adopted: "Resolved, That this association cordially endorse the plan proposed by the committee of reorganization for a uniform system of organization of State and county societies in affiliation with this body, and the secretary is hereby instructed to correspond with the officers of each State society and urge the adoption of such plan in so far as it may be applicable, and that he shall report to the next annual meeting the result of such correspondence."

Report of the General Executive Committee.—After considerable discussion, it was decided to act upon this report by sections. Upon the recommendation of the committee the meeting passed a resolution of disapprobation of the action of Congress in failing to pass the bill providing for the proper recognition of the army corps.

The recommendation of the committee that the president appoint a special committee of three members to revise the code of ethics brought out a lively discussion.

It was finally decided that this recommendation be tabled.

The Oration in Medicine was delivered by Dr. N. S. Davis, Jr., of Chicago. (See page 978.)

The president announced that, as there seemed to be some misunderstanding regarding the reorganization scheme which had been adopted, he wished to state that its provisions went into effect in the present session only so far as they applied to the election of new delegates. All standing committees and all special committees appointed at the present session would stand and report at the next meeting.

The Oration in State Medicine was delivered by Dr. George M. Kober, of Washington, D. C. (See page 991.)

The London Tuberculosis Congress.—Dr. Judson Daland, of Philadelphia, was appointed to represent the association at the World's Tuberculosis Congress, to be held in London in July of the present year.

Report of the General Executive Committee.—Dr. L. D. Bulkley, of New York, the secretary of the committee, announced that Mr. John D. Rockefeller had recently given the sum of \$200,000 for the promotion of scientific research. This sum had been placed at the disposal of the association's committee, under the chairmanship of Dr. William H. Welch, of Baltimore. A resolution was adopted thanking Mr. Rockefeller for his generous gift.

Report of the Judicial Council.—Dr. F. H. Wiggin, of New York, read the names of a number of physicians and announced that the Judicial Council recommended that they be dropped from membership. The cause for this recommendation was either the non-payment of dues or the fact that the gentlemen were no longer in good standing in their affiliated State or county societies. The report of the council was adopted without comment.

Report of the Committee on National Legislation.—Dr. H. L. E. Johnson, the chairman of the committee, said that at the recent meeting of the National Association of Military Surgeons the following resolution was adopted:

"Resolved, That this body deplors the action of Congress in abolishing the army-post exchange, or canteen, and in the interest of discipline, morality, and sanitation recommends its reestablishment at the earliest possible date."

This resolution had been presented at one of the general sessions by Major L. L. Seaman, and the meeting was now asked to endorse the action taken by the National Association of Military Surgeons. It was referred to the Committee on National Legislation, who reported as follows:

"We have carefully considered the resolution proposed, and declare it to be wise and proper and of importance to every citizen of the republic. The resolution is the outgrowth of careful study and observation by the medical department of the United States army; is concurred in by the commanding officers at the several posts, and is intended to correct serious abuses under the present law, which result in drunkenness, desertion, insubordination, dishonorable discharge, crime, poverty, appalling increases in venereal disease, and invalidism among the soldiers of the United States army.

"We find that the experience of foreign governments coincides with that of the National Association of Military Surgeons in the necessity for the army-post exchange, or canteen.

"We recommend that the American Medical Associa-

tion adopt the resolution proposed, and that it petition the Congress of the United States to repeal at the earliest moment the objectionable law which prohibits the army-post exchange."

The recommendation of the Committee on National Legislation was unanimously adopted.

Introduction of the President-elect.—Dr. John A. Wyeth, of New York, the president-elect, was escorted to the platform by Dr. Marcy and Dr. Magruder and introduced by the retiring president, Dr. Reed, who said:

"The moment has arrived that I can relinquish the arduous duties of this office, and in doing so I feel that I am passing the work to one under whose guidance this association shall be kept true to its exalted purposes. I take pleasure, therefore, in introducing to you my successor, Professor Wyeth."

Dr. Wyeth responded briefly as follows: "I appreciate deeply the honor that has been conferred upon me. It will take my best efforts to repay the association, even in part, for what I have received, but, such as they are, it shall have them. In the future, as in the past, I will do what I can to advance the highest and noblest interests of medicine and surgery."

A motion was adopted thanking the retiring officials, the committee on arrangements, and the good people of St. Paul and Minneapolis for the splendid management of the convention.

In seconding this motion, Dr. H. O. Marcy, of Boston, one of the ex-presidents of the association, said: "For twenty-six years I have followed the good fortunes of this association from the Atlantic to the Pacific, from the north to the south. Everywhere we have been received with that open arm of welcome, that cordiality of spirit that becomes the American citizen. Twenty years ago we met in this city of St. Paul. Those of us who were present then will recall the splendid hospitality that the people and physicians of this city accorded us. Upon this occasion it has been magnified even out of proportion to the growth of these twin cities of the Northwest."

Section in Surgery and Anatomy.

(Concluded from page 1012.)

The Mortality of Appendicitis.—Dr. John B. Deaver, of Philadelphia, in a paper with this title, began by saying that during the year 1900 there were operated on at the German Hospital, in Philadelphia, 268 persons with appendicitis, of which 144 had acute attacks of the disease and 124 chronic. Of those operated on during the acute stage, twenty-six died from the appendicitis or from some intercurrent or previously existing disease. In the cases not subjected to surgical treatment, by far the most potent factor was septic peritonitis. As to the number of attacks, the author said that the fatal attack might be the "solitary severe one." Severe attacks without fatal issue subsided to varying degrees, but commonly rendered the internal symptoms more aggravated. In cases complicated with adhesions, but without septic infection, the mortality was very low. In one case the author had operated twelve hours after the onset of the attack and found an advanced general purulent peritonitis, a condition from which he had never seen a recovery. He believed that where there was localized pus, the success of the operation depended upon emptying and draining every pocket; merely opening and draining the main abscess would not do, the great problem being how to drain all these collections without infecting the general peritoneal cavity. Post-caecal collections of pus

offered a serious problem. As to the advisability of removing the appendix in the presence of pus, the opinion of the author was that it should be removed, except in certain cases. Another very common cause of death was necrosis of the bowel. Dr. Deaver's experience showed that recurrent attacks of appendicitis were progressive in their severity, each one adding fuel to the flame; that the position of the appendix was an important feature; that delay in operating was responsible for more deaths in appendicitis than all the other factors having to do with the disease; that an operation in the first twelve, and at the latest eighteen to twenty-four hours, would save patients without subsequent complications, such as faecal fistula, etc.

Some Unusual Features of Appendicitis and their Treatment.—Dr. Ernest Laplace, of Philadelphia, said, in a paper thus entitled, that in every case of fatal appendicitis there was a time when, had the operation been performed, the patient would have survived. He was of the opinion that it was not the appendicitis that killed, but the peritonitis incident thereto. He divided appendicitis into three different periods or stages: 1. That of appendicitis. 2. That of peritonitis. 3. That of septicæmia. He believed in rapid operative procedure in peritonitis from chronic appendicular abscess that had perforated or an acute peritonitis set up by appendicitis. Careful cleansing of the operative field should be instituted, with flushing of the abdominal cavity. When septicæmia and peritonitis were both present, then he would simply wash out the abdominal cavity, close it, and drain with gauze. He believed that it must be taken for granted that the phagocytes would compete more successfully with a slight amount of septicæmia than with septicæmia which was continually increasing by constantly forming toxins taken up from the peritonitis. Continuous flushing of the peritoneal cavity for at least a few hours after the operation would constitute the local treatment, whereby the arrest of progressive septicæmia might be hoped for.

The Knot within the Lumen in Intestinal Surgery, with Report of Eight Cases, was the title of a paper by Dr. F. Gregory Connell, of Chicago. The author said that the possibility of placing all the knots in enterorrhaphy within the lumen was no longer in doubt, but the advisability of such a procedure was still a disputed question by those who never used it. In no case could death be attributed either to the method of suture employed or to the manner of employing it; to include all the coats of the bowel-wall removed the danger of stitch yielding; to fail to include the submucosa left an insecure stitch; and it was not only possible, but practicable, to place all the knots of an enterorrhaphy in the lumen.

Dr. J. B. Murphy, of Chicago, commended Dr. Deaver for his work on this important line, styling it a debt of gratitude which the profession would never be able to pay. He considered that the question as to whether it was possible to make a diagnosis of the pathological conditions within the peritoneal cavity from the symptoms presented was a very vital one. In the fulminating type the speaker did not believe that one could tell from the outside whether it was progressing to that stage where it manifested its virulence.

Dr. Knight, of Connecticut, believed in the great helpfulness, if not the reliability, of the presence of leucocytosis as an indication of the condition.

Dr. Maxwell, of Iowa, endorsed thorough irrigation of the abdomen.

Dr. Andrews, of Chicago, spoke of the length of time of infection. "How do we know," he asked, "what the conditions are when we find free pus in the intestines without the restraining wall?" He believed that around this area of pus there was another zone of mucopus or serum.

Dr. Harris, of Chicago, did not believe that we were able to ascertain the condition in the abdomen. When a man had operated upon one hundred cases, he found he knew little or nothing about the conditions therein.

Dr. Moore, of Minneapolis, did not think there should be any hard-and-fast rule to be laid down in surgery where human life was involved. The question of operating should likewise be considered from the standpoint of environment; every one did not possess the advantages of a well-equipped hospital, such as existed in the large cities.

Dr. Morris, of New York, said that in appendicitis we were dealing with an infection the limits of which were unknown.

Dr. Smythe, of Memphis, said that the proper treatment of the patient was surgical.

The Nature of the Cancerous Process.—In a paper thus entitled, Dr. Roswell Park, of Buffalo, said that, like a huge and frowning sphinx at the very gateway or entrance to the field of surgical pathology, had stood for centuries the great problem of the nature of cancer. This had, at least until recently, remained the inscrutable mystery of ages. The author held that the parasitic, or infectious, theory of cancer was the only one which satisfied the needs of both pathologist and clinician.

In the New York State Laboratory, with which Dr. Park was connected, the disease was studied by the pathologist, biologist, chemist, histologist, and clinician, all working in close association. As to causation, the author was of the opinion that cancer was due to an extrinsic cause, parasitic in its nature. He took the analogy of vegetable life to sustain the parasitic theory, stating that the woody masses or xylomata, or knots, in trees, which suggested the tumor or cancer idea, destroyed the tree; they were frequently spoken of as tree cancers. Tumors were also common in the lower animals. He believed that tumors in man and animals were due to the same general causes, and thought it was not too strong a statement to make that Dr. Gaylord and the laboratory staff had absolutely produced adenocarcinoma by inoculation in a number of animals, and that this could be produced in such a way as to afford unmistakable evidences of the infectiousness of the disease.

The Present Status of the Carcinoma Question.—Dr. Nicholas Senn, of Chicago, considered this the most important research of to-day. Carcinoma resulted from atypical proliferation of epithelial cells. As carcinoma originated in epithelial cells, its development was impossible in mesoblastic tissues. Histology did not support the parasitic theory. The progressive extension of a tumor into the adjacent tissues was proof positive of malignancy. It was by the lymphatics only. The increase of carcinoma was more imaginary than real. There was more basis to heredity than was believed by the profession at large. The age was important; although usually occurring after forty, it might develop before twenty, and in these cases it was almost invariably extremely malignant.

The Early Diagnosis of Carcinoma—Methods.—Dr. Charles A. Powers, of Denver, said the salient features

he desired to bring forward were early recognition, thorough operative removal of the widest possible area, and a careful, systematic surveillance of the patient during the rest of his life. The laity should be instructed upon these points. The author reviewed the diagnostic reaction of the use of cancer serum and auto-inoculation as aids in the early diagnosis of cancer.

The Pathology of Breast Carcinoma and its Relation to Early Diagnosis and Treatment.—Dr. William S. Halsted and Dr. J. C. Bloodgood, of Baltimore, grouped the tumors under multiple, malignant, and benign and those associated with various acinous changes in the tissues of the breast. They said: "In our experience of some 294 cases, the number of cases of malignant tumors which have been admitted to the hospital at such an early stage that the clinical picture was suggestive of a benign tumor, is about nine per cent., or about twenty-three cases. What it will be in the future we are not prepared to say."

Carcinoma of the Cæcum.—Dr. William J. Mayo, of Rochester, Minn., believed that carcinoma of the cæcum constituted seven per cent. of all cancers of the intestines, and was of the columnar-cell variety. Colloidal changes were frequent. It was usually annular in form, but might present a well-marked tumor. Glandular infection occurred in fewer than one half of the cases of death from this malady. Age was not so important a feature as in carcinoma of other organs. It was not infrequent in the comparatively young. This disease might be confounded with chronic appendicitis, tuberculosis of the cæcum, fecal impaction, etc. The results of radical operations, both immediate and remote, were good and compared favorably with those for cancer in other situations of the body.

An Improved Method for Resecting High Rectal Carcinoma.—Dr. Robert F. Weir, of New York, considered the Kraske operation unsatisfactory for the removal of high-seated cancers of the rectum, and preferred Maunsell's method. He especially covered the technic of high rectal operations and gave an interesting list of cases.

The Treatment of Malignant Disease.—Dr. Frederic S. Dennis, of New York, considered surgery, toxines, drugs, caustics, electricity, and the Röntgen rays. A surgical operation was successful only when it was performed early, when it was radical in character, and when it was repeated indefinitely. Patients were not considered cured unless three years at least had elapsed since an operation, and by some this period was estimated as too short. The importance of education of physicians as to the necessity of an early operation as the essential feature of cure should be borne in mind, as well as the importance of microscopical examinations of every growth as the only means to obtain accurate information for the future study of malignant disease. It was necessary to keep a careful record of every case, with its subsequent history. He said that the increase of cancer was not explainable. He was of the opinion that the action of the toxines upon malignant tumors was only explainable upon the theory that such tumors were the result of some infectious micro-organism, and this view was strongly supported by the recent opinion of Czerny. Surgical intervention was the only resource, since all drugs had proved ineffectual.

Dr. A. C. Bernays, of St. Louis, believed that in cancer we had to face an endemic disease, and that it affected all classes. Dared we hope for a curative remedy? He thought not. Many men had worked on this question, but all had failed to solve the nature of cancer.

As to ætiology, some growths, he thought, were of an embryonal nature, some parasitic, and others rudimentary. He thought we might hope to exercise a sort of prophylaxis as we now did in tuberculosis.

Dr. Crile, of Cleveland, spoke of a screw-clamp to close the arteries, and thus prevent hæmorrhage, in the operation for cancer of the tongue.

Dr. Rodman, of Philadelphia, said there was accumulated evidence to show that carcinoma was of parasitic origin. Until recently it had been supposed that carcinoma was not found so frequently in the Indian and in the negro, yet it was found in both those races. Certainly this is true of carcinoma of the breast, and in the negro it was probably somewhat more common than in whites.

Dr. Fütterer, of Chicago, was opposed to the parasitic theory, but did not wish to discourage research along that line. He referred to the mechanical theory, the displacement of the epithelial cells in the deeper layers, and the Cohnheim theory.

Dr. Massey, of Philadelphia, thought that cancer was a separate entity, separate from the man or woman on which the disease fed. He spoke of the use of the electric current, causing immediate chemical disintegration of the growth under ether.

Dr. Robert H. M. Dawbarn, of New York, commended the method of Dr. Halsted and Dr. Bloodgood in the extirpation of tumors or lumps in the breast, whatsoever they might be. In operations for cancer of the tongue he believed death was caused by shock and that the chief cause of shock was hæmorrhage.

Dr. Leavings, of Milwaukee, referring to cancerous growths coming from a development of epithelial cells, embryonal or post-natal in character, drew an analogy between this and the embryology of the teeth and the enamel organ.

Dr. McKenzie, of Oregon, spoke from the standpoint of the clinician. He thought that, in considering the origin of cancer, the point of locality had a great deal to do with it, and that when it developed in any part of the human body it did so in tissues which were not normal anatomically and in organs which were not normal physiologically.

A Method for the Study of Relational Anatomy.—

Dr. C. M. Jackson, of the University of Missouri, gave an interesting talk on this subject, in which he said that the relative inefficiency of the present courses of instruction in anatomy was largely due to the lack of a practical method of studying the topographical relations of the various organs. For this purpose sections were necessary. The method of employing frozen sections he considered unsatisfactory. The author had obtained excellent results by sectioning bodies hardened by arterial injections of formalin. He gave a detailed account of this method as applied in teaching relational anatomy in the University of Missouri, and exhibited a new apparatus for making rapid and accurate drawings of sections.

Hæmostasis in Amputation at the Hip Joint—*A Résumé of 267 Cases by the Author's Method*, was the title of a paper by Dr. John A. Wyeth, of New York. During the past eleven years the author had collected 267 cases in which the operation had been done. It had first been made public at a meeting of the American Medical Association in Nashville, in 1890. The 267 cases were classified as to neoplasms, sarcoma, epithelioma, and osteocarcinoma. While the mortality was large, the lesions were of a very severe type. The death

rate in 1881, from all causes, was 64 per cent.; it was now 19.8 per cent. The death rate twenty years ago, from all causes, was equal to that for crushing accidents from railway trucks or heavy machinery at this date. Antisepsis must share with the improved hæmostasis the credit of this diminished rate of mortality.

Dr. Means, of Columbus, stated that his experience had been limited to two cases. He thought that the use of these pins in hæmostasis could be extended quite as well to various other portions of the body. He felt that the profession should congratulate Dr. Wyeth on this method of controlling hæmorrhage.

Dr. Walker said that the ease with which hæmorrhage could be controlled was a revelation to him. He asked why the operation could not be done without the use of the pins. Why not do the ligation primarily?

Dr. Sylvester considered it a very scientific and satisfactory operation. He was in the habit of tying the silk-worm sutures in bow-knots, which could be untied without the use of an anæsthetic.

Dr. Wright, of Bridgeport, Conn., used a heavy rubber bandage and converted it into a roll, passing it around the groin. He had thus been able to produce an hæmastasis which was quite satisfactory. It occluded the vessels and saved the necessity of the pins.

Autoplastic Suture in Hernia and other Ventral Wounds.—Dr. L. L. McArthur, of Chicago, in a paper on this subject, said that, as to suture material, he would not have presented the paper if he did not believe that his method possessed strong merits, viz.: 1. The obtaining of a living suture. 2. Lessened chance of failure through avoidance of the introduction of dead or foreign tissue. 3. The incorporation in the resisting cicatrix of organized white fibrous tissue. He felt that failure of cure in hernia operations by any of the recognized methods was practically due to associated infection, for the Bassini, the Andrews, or the Girard method, unassociated with infection, could be said to be practically always successful.

Dr. Powers, of Denver, believed that Dr. McArthur's proposition was well worthy of trial. He did not know whether the essayist had operated on any children by this method.

Dr. G. F. Shimonek, of Milwaukee, believed that this tissue, so united, was of rather low vitality, as all tissues of that kind were, and that by passing it through the opening and putting it on a stretch it must become devitalized.

The chairman called attention to the fact that there was no tension after suturing. There was no constriction, as occurred when the tissues were tied with catgut.

Dr. McArthur said he had found that the edge did not tear out any more than it would in using any other suture material. The speaker reported a case of a rather rare type of hernia, which was spoken of as the "sacless hernia."

A New Method of Skiagraphic Diagnosis for Renal and Ureteral Surgery.—Dr. L. E. Schmidt and Dr. G. Kolischer, of Chicago, referred to the fact that skiagraphy for medical purposes had been especially advanced and perfected in America, and stated that calculous deposits were particularly attractive for x-ray diagnosis. The authors' paper was elucidated by illustration, one showing a kidney and a renal stone. By their method they were able to determine the course of the ureters, the location of the renal pelvis, the degree of dilatation

of the renal pelvis, and the situation of renal calculi; also to distinguish gall-stones from renal stones.

Prostatotomy versus Prostatectomy for Prostatic Hypertrophy.—Dr. Ramon Guitéras, of New York, outlined the history of prostatectomy and prostatotomy, stating that each had been developed by a gradual evolution. His personal preference was for the vesicorectal method, and the most important part of his technics was the inserting of two fingers high up in the rectum. It was too grave a condition—senile hypertrophy of the prostate—to allow of dogmatizing. There were three important classes of these cases: The first, the physiological young, suitable for radical operation; the second, elder, could withstand the palliative Bottini method. The third class, fortunately small, and growing smaller, were able to undergo no operation whatsoever. Statistics showed the mortality of prostatectomy to be three times that of prostatotomy.

Prostatectomy the Method of Choice in the Management of Prostatic Obstruction.—Dr. Eugene Fuller, of New York, opened his paper with a plea for radical operative relief in these cases. At the present time, if a practitioner allowed a patient to die from appendicitis without resorting to surgery, or, at least, to asking for surgical interference, the community at large blamed him severely; the same ought to apply to prostatic obstructions. With proper surgical management, the mortality of prostatectomy, under favorable circumstances, was not over from 8 to 10 per cent. Castration for the relief of this condition Dr. Fuller cast aside as a discarded method. The Bottini method was also considered.

A Further Report on Permanent Catheterism.—Dr. J. Rilus Eastman, of Indianapolis, in a paper on this subject, said that permanent catheterism in the male had been practised by him in fifteen cases; in each case the catheter being retained for at least ten days and in two cases for sixty days. The cystitis which occurred in the author's cases was not sufficiently severe to produce symptoms. Hydrogen peroxide was introduced into the bladder. Regular flushing of the bladder had been done in only two cases. It was essential that the catheter be introduced just far enough so that the tip should project into the bladder and be accurately secured.

Perineal Prostatectomy.—Dr. Parker Syms, of New York, said in a paper that, while prostatectomy by most methods had shown a large death rate, he had thus far been fortunate in not having lost a patient and in having obtained a complete cure in all his cases except one.

Dr. Robert H. M. Dawbarn demonstrated his apparatus for suprapubic drainage, which had already been tested for ten years.

Dr. Rockery regarded the question of prostatic hypertrophy as one of vastly greater importance than it seemed to be considered by the profession. He believed the operation of prostatectomy had been an evolution, and that the question to decide was as to the method. He thought the operation should be done earlier for the relief of this condition, and not left until it became the last resort.

Dr. McGowan, of Los Angeles, had operated on about fifty old men by prostatotomy and prostatectomy, the ages of the patients ranging from sixty-five to eighty-one years. The results had not been perfect by either method.

Dr. Guitéras, speaking of retention of urine, said that the bladder ought never to be emptied at once. Not

over a pint should be withdrawn the first time. Speaking of the Bottini operation, he said that it held the same position to-day as hysterectomy had held a few years ago. He hoped that some day an operation that could be done with ease and safety would be devised.

Pneumectomy and Pneumotomy.—Dr. J. B. Murphy, of Chicago, read a paper in which he said that pneumectomy was frequently indicated and could be performed with safety to the patient. The danger of pneumothorax was not great. Portions of the lung might be excised without danger of hæmorrhage and without the production of pneumothorax from division of the branches of the bronchi. Pneumotomy was also frequently indicated; it was not a dangerous procedure, and might be accomplished with or without adhesions of the lung; the hæmorrhage was easily controlled. The author showed why the scalpel should be used in place of the Paquelin cautery in opening pulmonary abscesses, interlobar abscess, and bronchiectatic cavities.

The Removal of Foreign Bodies from the Trachea and Bronchi.—Dr. DeForest Willard, of Philadelphia, said in his paper that foreign bodies, such as seeds, nuts, toys, food, etc., were exceedingly liable, especially in children, to be sucked into the trachea during laughing, crying, etc. The violent efforts at coughing usually dislodged the offending body if it had not reached the larynx, but it might be arrested at the vocal cords or pass on and become impacted in one of the bronchi (usually the right), from anatomical reasons. A low tracheotomy should at once be performed and a large opening made, when the object to be sought for was metallic, and x-ray representation might prove of great value. Should gangrene of the lung occur, a free incision should be made down to the pleura.

The Treatment of Empyema.—Dr. James H. Dunn, of Minneapolis, in a paper on this subject, said that the average treatment of empyema was still far from satisfactory and decidedly behind the present status of surgical science. He assigned as some of the causes of failure tardy diagnosis, inefficient drainage, and slovenly after-treatment. A pleural collection of pus should at once be removed. The drainage opening should be large.

Dr. Bernays said he believed the time had come when surgery should attack the ravages of tuberculosis in the lungs, and that it could be done successfully. The speaker then related some interesting post-mortem findings of tuberculous tissue. He believed that this department of surgery was still in its infancy. As to Dr. Dunn's paper, the speaker said that the treatment of empyema depended on the microscopical findings in the fluid that had been withdrawn by the exploratory needle.

Dr. William Jepson, of Iowa, considered that the removal of foreign bodies from the air-passages formed an important part in general surgery; that in every instance of foreign body in the air-passages the trachea should be opened. He did not believe that emetics or holding the patient upside down would avail. He said that when the trachea was once opened we immediately knew whether the foreign body was near the distal or the proximal opening, and whether it was toward the lung or in the larynx. If it was in the larynx, it could easily be removed with the forceps.

Dr. Frank, of Chicago, said that, from his experience in two cases of lung surgery and from experiments on dogs, he had come to the conclusion that surgery of the lung was not so easy as most of the speakers would lead one to believe.

Dr. Norred, of Minnesota, related the case of a child,

two years and a half of age, who had swallowed a peanut kernel, which was drawn into the bifurcation of the trachea. His two consultants said there was no hope, but he persisted and suggested that they relax the child completely, and thus prevent any muscular contraction. The child was thereupon given apomorphine and vomiting was provoked, whereby the peanut kernel was dislodged and coughed up.

Dr. W. W. Keen, of Philadelphia, spoke in relation to puncture of the lungs. The points which he emphasized were the means of obtaining adhesions where none existed in puncturing the lung and the safety of a very large suture of lung tissue to the chest wall. In the first case the speaker made his incision parallel to the ribs for about two inches, carefully dissecting the muscles, separating them as he went down, until he reached the pleura. It was very easily recognized and the muscles were very readily separated from it. The other was the case of a woman who had a sarcoma of the chest wall, reaching from the outer border of the breast nearly all the way back to the vertebral column.

The Indications for Operation in Calculous Nephritis and Urethritis.—Dr. Charles L. Leonard, of Philadelphia, in a paper thus entitled, brought out the facts as follows: Recent advances in the diagnosis of calculous conditions of the kidneys and ureters showed that more than half the calculi that originated in the kidneys passed into the ureters before they occasioned sufficient symptoms to make their presence known, and the Röntgen-ray method of diagnosis had shown the greater frequency of ureteral calculi. Their detection did not, however, constitute an indication for operation. The distinction between the cases that demanded an operation and those suitable for palliative treatment was based on the use of the Röntgen-ray method of diagnosis. Its accuracy had been confirmed in 165 cases which the author had examined by this method. The author dwelt at some length upon the symptomatology, as well as the radical, conservative, and expectant treatment. While exploratory operations were valuable in many cases, yet the actual incision into the kidney was now only justified by the previous detection of a calculus by the Röntgen-ray method or some macroscopical pathological lesion. Ureterolithotomy had been successfully performed in many cases. One of the greatest problems of renal surgery was the determination of which kidney or ureter was the one upon which to operate, and at what point.

Acute Infective Cholangiitis and Cholecystitis as a Complication of Gall-stones.—Dr. Daniel N. Eisendrath, of Chicago, in a paper thus entitled, referred especially to the formation of stones produced by the colon and typhoid bacillus. These infective agents set up a catarrhal condition in the gall-bladder and bile-ducts. Gall-stones might remain in the gall-bladder for years without giving rise to the least suspicion of their presence. Whenever pus was present in the gall-bladder, especially if the symptoms had been acute, the prognosis should be guarded. There should never be delay in the treatment of an empyema of the gall-bladder complicating gall-stones.

Dissecting Abscesses of the Abdominal Wall, Producing Symptoms Simulating Pott's Disease of the Spine.—Dr. James B. Bullitt, of Louisville, read a paper in which he reported an illustrative case following typhoid fever, six weeks after the subsidence of the fever (kyphosis). Careful examination showed deformity

due to a collection of pus beneath the abdominal wall and extraperitoneal. The lumbar kyphosis was entirely compensatory. The abscess finally ruptured externally at the umbilicus and continued to discharge indefinitely a thin pus. The author gave a résumé of six cases collected from literature, with remarks.

Experimental and Clinical Observations on the Therapeutics of Abdominal Surgery.—This was the title of a paper by Dr. George W. Crile, of Cleveland, in whose absence and that of Dr. Howard A. Kelly, Dr. Frank D. Smythe, of Memphis, opened the discussion. He reported a case of cystitis and kidney stone for which both cystotomy and nephrectomy had been performed, the kidney showing signs of gonorrhœal infection. He said that jaundice was not a contraindication to a surgical operation in his experience.

Dr. McGowen discussed the efficacy of the x ray in the diagnosis of the kidney or ureter, and mentioned two serious burns that had occurred in his experience.

Dr. Thomas, of Pittsburgh, mentioned a case of stone in the kidney in which an x-ray picture had failed to show the presence of the stone. The kidney, however, was incised and the stone discovered.

Dr. Crane, of Vermont, who had had considerable experience in x-ray work, said that the shadow cast was dependent on the atomic weight of the substance. As regarded examinations for stone, different kinds of stone cast shadows of varying density. The oxalate-of-calcium stone would cast a dense shadow as compared with that of the uric-acid stone. He thought the danger of x-ray work came entirely from the length of exposure at too short a distance from the Crookes's tube. Asked by a member what he considered the proper distance and length of exposure Dr. Crane replied: "Within two or three inches from the tube and an exposure of not more than three minutes. A longer exposure should be with a correspondingly increased distance from the tube."

Dr. Means, of Columbus, believed that the bile-passages normally contained micro-organisms. He said it was a dangerous statement to make that gall-stones might be in the gall-bladder for years or for an indefinite period and produce no symptoms.

Dr. Davis, of Omaha, spoke of the "clumping" of the typhoid bacillus, which constituted a nucleus around which the stones formed.

Dr. Rodman, of Philadelphia, was very optimistic as regarded the production of burns by the Röntgen rays, believing that in proper hands there was no cause for alarm.

Dr. Bloodgood, of Baltimore, spoke of acute hæmorrhagic pancreatitis; also of cases in which there was a history of gall-stone colic, with or without jaundice, and yet, when he operated, he found no stones in the gall-bladder or ducts, but an indurated pancreas or chronic interstitial pancreatitis, and he found such cases were relieved by temporary drainage of the gall-bladder.

Fracture of the Femoral Neck was the subject of a paper by Dr. C. E. Ruth, of Keokuk, who recited many cases, particularly that of a man, seventy-two years of age, who sustained a fracture of the femoral neck at that time, and died eighteen years afterward, at the age of ninety. Dr. Ruth exhibited this specimen, which showed that bony union had taken place.

Dr. Thomson, of Scranton, exhibited an x-ray specimen of fracture of the neck of the femur in a miner who had been under his care. The patient had eventually died from heart trouble.

Letters to the Editor.

ABSORBENT COTTON FOR HÆMOSTATIC TAMPONS.

NEW YORK, May 20, 1901.

To the Editor of the *New York Medical Journal*:

SIR: In regard to the criticism of Dr. Edwin R. Chadbourne, of Pasadena, Cal., on page 876 of your *Journal*, about the use of absorbent cotton (soaked in a two-per-cent. solution of carbolic acid) in the case of uterine hæmorrhage, of which I wrote you, and my account of which appeared in your *Journal*, on page 698, I will state that if the packing is done in the proper manner, compressing the several discs sufficiently, thereby making the tampon as solid a mass as the patient is able to stand, no obstetrician need have any fear of the result. I respectfully refer Dr. Chadbourne to H. Marion Sims, on the hæmorrhage of premature labor, and Braun, of Vienna, on the hæmorrhage of placenta prævia. I am glad to see my distant brother physician take such an interest in my little case, and would ask him to kindly give through the *New York Medical Journal* his diagnosis of the case, as originally requested.

P. M. MILLER, M. D.

HEREDITY AND APPENDICULAR DISEASE.

61 AUBURNDALE PLACE,
CINCINNATI, June 10, 1901.

To the Editor of the *New York Medical Journal*:

SIR: I am trying to establish the fact, which I believe to be true from my own personal observation (see *Lancet-Clinic*, June 8th), of an inherited tendency or predisposition to *appendicitis*. If the readers of your *Journal* will kindly look into the history (family) of their cases and report to me I shall be under very many obligations.

W. H. DEWITT, M. D.

Book Notices.

Obstetric and Gynæcologic Nursing. By EDWARD P. DAVIS, A. M., M. D., Professor of Obstetrics in the Jefferson Medical College of Philadelphia, etc. Illustrated. Pp. 3 to 402. Philadelphia: W. B. Saunders & Company, 1901.

THE author has collected in this volume his lectures to nurses on the subjects embraced in the title. The duties of the nurse in all phases of obstetric practice and in the care of normal and abnormal infants are dwelt upon at length and in detail in the first section of the book. The second portion of the work is devoted to gynæcologic nursing, and includes such themes as the posture of patients, douches, preparations for operations, remote and immediate, and a very ample and excellent chapter on the after-care of patients. While the book contains, we think, much more than the average trained nurse need know, it is written in accord with the present-day belief in the education of nurses, that they should be instructed very much as though they would some time be physicians. This is not said so much in criticism as to emphasize the full detail which one finds recorded. The rich experience of Dr. Davis has been called into requisition by him, and his book abounds in instructive material. The excellent illustrations and effective making of the book increase its value. After a very careful perusal of the book, we can cordially recommend it to training

schools for the use of their pupils; it would be hard to find anything better.

La peste d'Alexandrie en 1899 au point de vue clinique, épidémiologique, etc. Par le Dr. A. VALASSOPOULO, Médecin en chef de l'Hôpital grec d'Alexandrie. Avec figures et cartes dans le texte. Paris: A. Maloine, 1901. Pp. 3 to 164.

THIS monograph, dealing with the epidemic of bubonic plague in Alexandria, Egypt, received honorable mention from the French Academy of Medicine. It describes the first cases in that city, the subsequent development of the epidemic and its decline. The clinical aspects of the disease are satisfactorily presented, as are its anomalous forms and varieties. The bacteriology and morbid anatomy of the disease find sufficient mention. The monograph is interesting and valuable to students of epidemiology.

BOOKS, ETC., RECEIVED.

Surgical Experiences in South Africa, 1899-1900. Being Mainly a Clinical Study of the Nature and Effects of Injuries Produced by Bullets of Small Calibre. By George Henry Makins, F. R. C. S., Surgeon to St. Thomas's Hospital, London, etc. Philadelphia: P. Blakiston's Son & Company, 1901. Pp. xvi-493. [Price, \$4.]

A System of Physiologic Therapeutics. A Practical Exposition of the Methods, other than Drug-giving, Useful in the Treatment of the Sick. Edited by Solomon Solis-Cohen, A. M., M. D., Professor of Medicine and Therapeutics in the Philadelphia Polyclinic, etc. Volume II, Electrotherapy. By George W. Jacoby, M. D., Consulting Neurologist to the German Hospital, New York, etc. In Two Books. Book II, Diagnosis—Therapeutics. Philadelphia: P. Blakiston's Son & Company, 1901. Pp. xii-17 to 323.

Lectures on the History of Physiology during the Sixteenth, Seventeenth, and Eighteenth Centuries. By Sir M. Foster, K. C. B., M. P., M. D., D. C. L., Sec. R. S., Professor of Physiology in the University of Cambridge, etc., London: H. K. Lewis. New York: Macmillan & Company, 1901. Pp. 310.

How to Cook for the Sick and Convalescent. Arranged for the Physician, Trained Nurse, and Home Use. By Helena V. Sachse, Graduate of the Philadelphia Cooking School. Philadelphia: J. B. Lippincott Company, 1901. Pp. xvi-7 to 239.

The Practice of Charity, Individual, Associated, and Organized. By Edward Thomas Devine, Ph. D. (Penna.), General Secretary of the Charity Organization Society of the City of New York. New York: Lenthilhon & Company, 1901. Pp. x-186.

Year-book of the United States. Department of Agriculture, 1900.

Compendium der Physiologie des Menschen. Für Studierende und Aerzte. Zweite, verbesserte und vermehrte Auflage. Von Dr. Paul Schultz, Privatdocent und Assistent am kgl. physiologischen Institut der Universität Berlin. Mit 47 Abbildungen im Texte und einer lithogr. Tafel. Berlin: S. Karger, 1901. Pp. 364.

Kurzes Lehrbuch der Gynäkologie. Herausgegeben von Dr. Otto Küstner, o. ö. Professor, Direktor der Universitätsfrauenklinik in Breslau, etc. Mit 260 Abbildungen im Texte. Jena: Gustav Fischer, 1901. Pp. x-465.

Die Hypertrophie der Rachentonsille. Eine Monographie. Von Professor Dr. G. Gradenigo, in Turin. Mit 3 Tafeln und 45 Abbildungen im Texte. Viertel

Band. Viertes Heft. Jena: Gustav Fischer, 1901. Pp. 181 to 392.

Geburtshilfliche Operationslehre. Für Studierende Aerzte. Von Dr. Felix Skutsch, a. o. Professor an der Universität Jena. Mit 145 Abbildungen im Texte. Jena: Gustav Fischer, 1901. Pp. x-348.

Einführung in das Studium der Malariakrankheiten mit besonderer Berücksichtigung der Technik. Ein Leitfaden für Schiffs- und Colonialärzte. Von Dr. Reinhold Ruge, Kommandirt zum Institut für Infektionskrankheiten in Berlin, etc. Mit 2 photographischen Sowie einer lithographischen Tafel, 19 Abbildungen und 27 Fieberkurven im Texte. Jena: Gustav Fischer, 1901. Pp. 139.

Die Gicht-therapie in Karlsbad. Nach Neueren Grundsätzen. Dargestellt für die Aerztliche Praxis. Von Dr. Richard Sachs, Brunnenarzt, Kurarzt des oesterr. und deutschen Eisenbahnbeamtenverbandes in Karlsbad. Berlin: S. Karger, 1901. Pp. 48.

Topographischer Atlas der Medizinisch-chirurgischen Diagnostik. Von Dr. E. Ponfick, o. ö. Professor und Direktor des pathologischen Instituts zu Breslau. Erste Lieferung. Jena: Gustav Fischer, 1901.

Physikalisch-diätetische Behandlung der Magenkrankheiten in der Praxis. Mit Anhang; Kochrecepte. Von Dr. Albert Wittgenstein, Cassel. Leipzig: C. G. Naumann, 1901. Pp. vi-127.

Miscellany.

Blows on the Head and the Respiratory Centre.—Dr. W. N. Bullard (*Journal of Nervous and Mental Diseases*, November, 1900) reports some experiments performed at the physiological laboratory of the Harvard Medical School.

The experiments show that the normal brain pressure, as evidenced by the bulging of the uninjured brain of an etherized cat through an opening left after removal of dura and bone, unless pressure is applied to keep it in place, is increased by every factor increasing the general blood pressure. A cry (raising thoracic pressure), any general muscular movement, stimulation of the sciatic nerve, the administration of ether (increasing the heart's action), all demand a stronger pressure to keep the brain level. Pulsations after hæmorrhage are increased, but the actual brain pressure is less. After heavy blows on the skull, the pressure needed to prevent the brain from bulging is greatly increased. Experiments thus far fail to show that there is any increase of general arterial pressure to account for the greater brain pressure after injury. No observations have, as yet, been made to ascertain if the increase is to any degree dependent on increased cerebral venous pressure.

The practical application of these experiments lies in the confirmation of the views of Kramer, Polis, and Horsley, that the *respiratory centre is the first to be affected after a blow on the head*. Many times when respiration has ceased, artificial respiration for a few minutes has been followed by normal breathing which has continued for hours.

Hydatid Disease of the Heart.—Dr. A. Jeffrey-Wood (*Intercolonial Medical Journal*, March 20th) says that cases of hydatid disease of the heart are of sufficient rarity to be classed as pathological curiosities, and therefore puts on record the case of a man, twenty-eight years of age, a worker in a roller flour mill, who was riding his

bicycle slowly down a gentle slope, when he was noticed to suddenly fall forward on to the handles. The bicycle stopped and toppled over to the left; the rider did not put out either leg or arm to save himself, and fell with the bicycle between his legs. A bystander ran to his assistance, pulled his bicycle away, and carried him to the foot-path. Two ineffective gasps were given, when the pulse ceased, and the man was dead. His wife stated that her husband had enjoyed excellent health during the eight years they had been married, and during that time had only been away from work for a week, when he had an attack of influenza. During the seven months previous to his death he had complained of pains in his back at times, and had consulted two medical men, who both warned him not to ride a bicycle. He had never apparently been short of breath, or suffered from fainting. His fellow workmen said he was a very active fellow, and used to get off and on to the lift in very quick time.

At autopsy, August 27, 1900, twenty hours after death, the body was found to be of slight build, and the pallor of skin suggested death from hæmorrhage. On opening the thoracic cavity, the heart, closely covered by the pericardium, was seen to occupy the greater part of the chest, neither of the lungs being visible. The pericardium, though closely adherent to the surface of the heart, was with a little force easily detached; but, toward the base of the heart on the left side, a white patch showed through the pericardium, and as the covering was lifted from this part, a daughter-cyst, the size of a large marble, escaped from a large mother-cyst in the left ventricular wall. In removing the heart, about a dozen daughter-cysts escaped, two of them being as large as bantam's eggs. The right ventricle was very small, but the left ventricle was much hypertrophied. The heart weighed twenty-eight ounces and contained a little dark fluid blood, with a few very small clots. Each lung was lying at the back of the thoracic cavity, firmly adherent to the posterior part of the chest by old pleuritic adhesions. The right lung, on section, showed white frothy fluid on pressure; but the left lung was almost foetal in structure, bearing evidence of considerable pressure, and showing no froth on pressure. The liver presented a small retrograding cyst, the size of a large walnut, on the edge of the right lobe; and a small cyst about the same size, also containing pultaceous material, was found in the centre of an adhesion running between the lower edge of the liver and the duodenum. No other hydatid cyst was found; the rest of the organs were quite healthy.

Pneumonic Herpes.—M. Talamon (*Presse médicale*, April 24th) says that, between herpes zoster and pneumonia, there is more of a relation than a coincidence; the two affections have certain microbic connections, demonstrable by numerous examples. It is evident that the vesicle of zona is not produced directly by the pneumococcus, but is an expression of trophic trouble of the skin, the consequence of irritation or inflammation of nerve filaments. If the zona is intercostal and is superposed on the pneumonia, it may be supposed that there is propagation by extension of the pneumonic infection from the lung to the nerve. But if the herpes appears at a distance, only the action of the pneumotoxine on the nervous system can be blamed. M. Talamon, therefore, thinks it necessary to reverse M. Fernet's recent proposition and, instead of saying that pneumonia is a herpes of the pneumogastric, to say that zona is in certain cases a pneumococcal infection of the skin.

Original Communications.

RABELAIS AS A PHYSIOLOGIST; REFLECTIONS SUGGESTED BY HIS DESCRIPTION OF THE PRODUCTION AND MOVEMENTS OF THE BLOOD, IN 1546.

BY AUSTIN FLINT, M. D., LL. D.,

NEW YORK,

PROFESSOR OF PHYSIOLOGY IN THE CORNELL UNIVERSITY MEDICAL
COLLEGE.

IT is difficult to put oneself in a position to appreciate, with a reasonable degree of accuracy, the condition of knowledge common to scientific men of the period upon any one subject, at a time so remote as three and a half centuries; yet I have attempted to do this in respect to knowledge of the movements of the blood, in the middle of the sixteenth century. One can hardly imagine an accurate and useful knowledge of the physiology of nutrition, absorption, digestion, respiration, or secretion as existing before the discovery of the circulation by Harvey, in 1616; and this discovery was so momentous in its influence upon the science of medicine that its history anterior to the publication of the *Exercitatio anatomica de motu cordis et sanguinis* (1628) has been, perhaps, the most interesting chapter in the literature of physiology. Not only did this great discovery mark one of the most important epochs in human knowledge, but it indicated a method of observation of phenomena, and of reasoning from such observation, that has been of inestimable value to all succeeding generations. Flourens, in his history of the discovery of the circulation, says that "this little book of an hundred pages is the most beautiful book in physiology." Harvey's book was nearly contemporaneous with the *Novum organum and Advancement of Learning* of Bacon and with the immortal studies of humanity by Shakespeare. Did Harvey, as a disciple, follow the methods of inductive science founded by Bacon or did Bacon formulate a method suggested by the researches of Harvey, or were these two great minds independent of each other? These are questions that cannot be satisfactorily answered. All that can now be said is that the great investigator and discoverer illustrated the scientific method indicated by the great philosopher.

In the history of the development of the doctrine of the circulation, everything relating to the blood and its movements is of interest. Perhaps the most exhaustive and accurate account of knowledge of physiology anterior to the time of Harvey is in the encyclopædic work of Milne Edwards (*Leçons sur la physiologie*, Paris, 1858-1881), in twenty-four volumes, from which I have taken many citations.*

It is said by a writer in the fifth century that venesection was practised by the surgeons of the army of Aga-

*Milne Edwards, *Leçons sur la physiologie*, Paris, 1858, tome III, p. 2, et seq.

memnon in the siege of Troy. The tradition is that Troy was besieged for ten years and fell 1183 B. C. (Eratosthenes); one writer, however, fixes the date at 1335 B. C., and another at 1149 B. C. In the time of Hippocrates (460-377 B. C.) bleeding was practised from several different veins, the situations of which were well known. Aristotle (384-322 B. C.) was the first to show that the vena cava and the aorta communicated with the heart, and that the aorta carried blood. It is said, however, that the distinction between the arteries and veins was known before the time of Hippocrates and was described by Diogenes of Apollonia in the fifth century B. C.

It is somewhat difficult to ascertain exactly the notions of Aristotle in regard to the arteries. In his work, called in translation *History of Animals*, he describes the passing of air from the lungs to the heart; while in his work, *On Parts of Animals*, he describes two vessels arising from the heart, which, as well as the heart, are filled with blood. The two works referred to are generally accepted as authentic. Milne Edwards cites the following from the work, *History of Animals*, as expressing the idea of Aristotle: "Vessels arise from the heart which go to the lungs, the branches of which divide like those of the trachea. . . . These branches have no communication with these vessels, but, by reciprocal contact, the vessels which come from the heart receive the air and pass it to the heart, where their trunks open." Milne Edwards says that Hippocrates, Aristotle, Herophilus, and Erasistratus (300 B. C.) distinguished between the arteries and the veins; that on examining dead bodies the veins are generally found gorged with blood, while the arteries are almost empty; and this circumstance had led all physiologists to think that the veins were the only blood-vessels and that the arteries were designed to carry air. Aristotle considered the latter tubes as forming, with the trachea, a vast system of pneumatic conduits. Hippocrates, however, was the first to describe the pulse; Aristotle recognized that the pulse was produced by the movement of blood. Herophilus studied the pulse more closely, established its synchronism with the heart, and distinguished clearly the two kinds of vessels which "connected" the lungs with the heart. Erasistratus noted the play of the valves of the heart. This state of knowledge and conjecture, with many contradictions, remained until the time of Galen (130-200 A. D.). Galen noted that the arteries discharged blood when opened. He demonstrated experimentally the fact that the arteries carried blood by including a portion of an artery between two ligatures, opening the part of the vessel thus separated from the rest of the vascular system and finding that it contained blood only. Further observations led him to the conclusion that the liquid was not identical in the veins and arteries, although there were communications between the two systems of vessels which permitted the blood to pass easily from one to the other.

It is easy to imagine the disastrous effect upon learning of the destruction of the great libraries of the School of Alexandria, which contained about 700,000 rolls, or volumes. The library in the Bruchium is said to have been destroyed by fire in the year 47 B. C., when Cæsar burned the fleet in the harbor, the flames accidentally extending to the library. Most authorities agree that the destruction of the Serapeum, ordered by Theodosius in 391 A. D., completed the work of extinction. Following the disappearance of this, the greatest existing collection of rolls, on all subjects and in all languages, there was a long period of decline of learning. One can hardly wonder, then, that a great interval separated the work of Galen from the next important date in the history of the physiology of the circulation—namely, the description of the pulmonary circulation by Servetus, in 1553. The literature of the Middle Ages, extending from the decline of the Roman Empire to the revival of letters, or, according to Hallam, from the beginning of the sixth to the end of the fifteenth century, is very meagre; and it is easy to understand the difficulty of ascertaining the extent of common knowledge of physiology during the first half of the sixteenth century.

It is certain, however, that, with the exception of the work of Servetus, the precursors of the discovery of the general circulation were almost entirely anatomical. In 1543 the great anatomist, Vesalius, corrected the error of Galen, who supposed that there were openings in the septum between the two ventricles of the heart. The valves of the veins were described by Étienne (1545), Cannanus (1551), Eustachius (1563), Piccolomini (1586), and Fabricius (1603). Fabricius demonstrated the valves in the veins to Harvey, probably in 1601 or 1602. In a copy of Harvey's original work (1628), which I presented to the Astor Library, is the following manuscript note by a former owner: "The valves in the heart and veins, the famous Dr. Harvey told me, gave him the first hint of his grand discovery.—Boyle."

François Rabelais (1490?-1553) universally recognized as "the greatest of French humorists and one of the few great humorists of the world" (Saintsbury), in the third book of his collected works (the second book *Treating of the Heroic Deeds and Sayings of the Good Pantagruel*), gives an account in Chapter IV, in which "Panurge continueth his discourse in praise of borrowers and lenders," of the nourishment of the microcosm and its members by the blood. In the collected works of Rabelais there are but two passages in which reference is made to movements of the blood; but these are so striking, in view of the work of Servetus, published in 1553, that it has seemed to me important, in connection with the history of the discovery of the circulation, to study these passages closely and critically. The book referred to was published in 1546, seven years before the date of the *Christianismi restitutio* of the unfortunate Serve-

tus; and I find no reference to this by any writer on physiology. The remarkable passage, which I shall give in full further on, is in one of the curious discourses of Panurge, the principal character in the books relating to Pantagruel. The writings of Rabelais, as they have come down to us, are works of quaintly extravagant and humorous fiction, in language which at the present day might be regarded as gross and even obscene; but, measured by the standard of the sixteenth century, they might not be so considered. As appearing in a work of fiction, it is hardly to be expected that great care as to accuracy of scientific statement would have been exercised, as probably was the case in the serious work of Servetus; but it must be borne in mind that Rabelais was a physician, had a thorough knowledge of the Latin and Greek languages and had given public lectures in 1531 on Galen and Hippocrates. In 1532 he edited the *Aphorisms* of Hippocrates and the *Ars parva* of Galen; in 1537 he lectured on the Greek text of Hippocrates, and in 1538 he made a public anatomical demonstration. Saintsbury, who has given, probably, the best brief account of the works and character of Rabelais, writes as follows: "With an immense erudition representing almost the whole of the knowledge of his time, with an untiring faculty of invention, with the judgment of a philosopher and the common sense of a man of the world, with an observation that let no characteristic of the time pass unobserved, and with a tenfold portion of the special Gallic gift of good-humoured satire, Rabelais united a height of speculation and depth of insight and a vein of poetical imagination rarely found in any writer, but altogether portentous when taken in conjunction with his other characteristics."

The beginning of the sixteenth century was also the beginning of the revival of letters. At the period when Rabelais and Servetus wrote, the accumulated learning of the world handed down to that time was to be found in a few works written in hardly more than two languages, Latin and Greek, and this is eminently true of scientific knowledge. The description of the pulmonary circulation by Servetus, in 1553, is certainly the most important event in the progress of physiology which led to the discovery of the circulation in 1616. I have endeavored, in my study of the literature, to ascertain how far Servetus was in advance of the scientific knowledge common to the learned men of his time. Where could I find this condition of knowledge more faithfully represented than in such portions of the works of Rabelais as referred to the subject under consideration?

The following are the passages in the works of Rabelais in which reference is made to the movements of the blood. I have endeavored to present a literal translation from the original old French, and have made but little use of the well-known translation by Urquhart and Motteux, which, though admirable and most faithful, is not exactly word for word:

"La vie consiste en sang; sang est le siège de l'ame; pourtant un seul labour poine ce monde, c'est forger sang continuellement. En ceste forge sont tous membres en office propre; et leur hiérarchie telle, que sans cesse l'un de l'autre emprunte, l'un à l'autre preste, l'un à l'autre est debteur. La matière est métal, convenable pour estre en sang transmué, est baillée par nature: pain et vin. En ces deux sont comprins toutes espèces de aliments. Et de ce est dict le compagne en langue Goth. Pour icelles trouver, préparer et cuire, travaillent les mains, cheminent les pieds et portent toute ceste machine: les yeulx tout conduisent. L'appétit, en l'orifice de l'estomach, moyennant de mélancholie aigrette, que lui est transmis de la ratelle, admoneste d'enfourner viande. La langue en fait l'essai; les dents la maschent; l'estomach la recoit, digère, et chyilifie. Les vènes mésaraiques en succent ce qu'est bon et idoine, delaisent les excréments, lesquels par vertus explosive sont vidés hors par exprès conduits; puis la portent au foye: il la transmue derechef, et en fait sang. Lors quelle joie pensez-vous estre entre ces officiers, quand ils ont vu ce ruisseau d'or, qui est leur seul restaurant? Plus grande n'est la joie des alchimistes quand après longs travaux, grand soing et despense, ils voient les métaulx transmues dedans leurs fourneaulx. Adonc chascun membre se prépare et s'estvertue de nouveau à purifier et affiner cestui thrésor. Les rognons, par les vènes émulgentes, en tirent l'aiguosité, que vous nommez urine et par les uretères la découllent en bas. Au bas trouve réceptacle propre: c'est la vessie, laquelle en temps opportun la vide hors. La ratelle en tire le terrestre et la lie, que vous nommez mélancholie. La bouteille du fiel en soustrait la cholère superflue. Puis est transporté en une autre officine, pour mieulx estre affiné: c'est le cœur, lequel, par ses mouvements diastoliques et systoliques, le subtilise et enflambe, tellement que par le ventricule dextre le met à perfection, et par les vènes l'envoye a tous les membres. Chascun membre l'attire à soi, et s'en alimente a sa guise: pieds, mains, yeulx, tout; et lors sont faicts debteurs, qui paravant estoient presteurs. Par le ventricule gauche il le faict tant subtile, qu'on le dict spirituel, et l'envoye a tous les membres par ses artères, pour l'autre sang des vènes eschauffer et esventer. Le poulmon ne cesse avecques ses

"Life consisteth in blood: blood is the seat of the soul; thus a single labour resteth upon this microcosm (*monde*), it is to make blood continually. In this workshop all the members are in proper function; and their hierarchy is such that incessantly the one borroweth from the other, the one lendeth to the other, the one is debtor to the other. The material is matter suitable to be converted into blood, is given by Nature: bread and wine. In these two are comprehended all kinds of aliments. And from this is said *compagne* in the Gothic tongue. To find, prepare, and cook these, the hands work, the feet walk and carry the entire machine: the eyes conduct all. The appetite, in the orifice of the stomach, by means of the sourish black humour, which is sent to it by the spleen, admonisheth it to shut in the meat. The tongue maketh the first trial of it; the teeth chew it; the stomach receiveth, digesteth and chylieth it. The mesenteric veins suck from it that which is good and fit, leaving behind the excrements, which by explosive faculty are emptied out by special conduits; afterward it is carried to the liver: it there changeth once again, and of it is made blood. Then what joy, think you, is amongst these officers, when they have seen this rivulet of gold which is their sole restorative? Greater is not the joy of alchemists when, after long labours, great care and expenditure, they see metals transmuted in their furnaces. Then every member preparereth itself and striveth anew to purify and refine this treasure. The kidneys, by the emulgent veins, take from it the aquosity which you call urine and by the ureters run it down. Below is found the proper receptacle: this is the bladder, which in convenient time emptieth it out. The spleen draweth from it the earthy part and the dregs, which you call black bile. The gall-bladder subtracteth from it the superfluous gall. Then is it transported to another workshop, in order to be better refined: this is the heart, which, by its diastolic and systolic movements, subtilizeth and heateth it, to such a degree that by the right ventricle it putteth it in perfection, and by the veins sendeth it to all the members. Every member attracteth it to itself and nourisheth itself from it in its own fashion: feet, hands, eyes, all; and then are made debtors, those which before were lenders. By the left ventricle it maketh it so subtile, that it is called spiritual, and sendeth it to all the

lobes et soufflets le refraischir. En recognoissances de ce bien, le cœur lui en départ le meilleur, par la vène artériale. Enfin, tant est affiné dedans le rets merveilleux, que, par après, en sont faicts les esperits animaux, moyennant lesquels elle imagine, discourt, juge, résout, délibère, ratiocine, et remémore."

Œuvres de FRANÇOIS RABELAIS, Paris, 1857, Livre III, Chapitre iv, page 152.

"Les philosophes et médecins afferment les esprits animaux sourde, naistre et pratiquer par le sang artériel purifié et affiné à perfection dedans le rets admirable, qui gist sous les ventricules du cerveau." *Ibid.*, Chap. xiii, page 159.

members by its arteries, in order the other blood of the veins to warm and winnow. The lung ceaseth not with its lobes and bellows to refresh it. In acknowledgement of which good, the heart distributeth to it the best of it, by the arterial vein. Finally is it so much refined within the *rete mirabile*, that, thereafter, are made of it the animal spirits, by means of which it imagineth, discourseth, judgeth, resolveth, deliberateth, ratiocinateth, and remembereth."

* * *
"The philosophers and physicians affirm that the animal spirits spring from, have their origin in, and operate through the arterial blood purified and refined to perfection within the *rete mirabile*, which lieth beneath the ventricles of the brain."

If it be assumed that Panurge, in this part of his discourse, represented ideas in regard to physiology that were generally accepted by learned men in the middle of the sixteenth century, it is seen that some of their notions were nearly correct.

He says that life consists in the blood and that through the blood there is a passage of material from one part of the body to another; that the material suitable to be converted into blood is food ("bread and wine; in these two are comprehended all kinds of aliments"); that the tongue tastes it, the teeth chew it, the stomach receives, digests, and chylieth it, which is a fair summary of knowledge of these processes, even up to the second quarter of the nineteenth century; that the mesenteric veins take up the nutritive constituents of the food, and that the residue is discharged from the body; that it (the food) is carried to the liver and there changes ("and of it is made blood"—the nutritive matters are actually changed in the liver, but, of course, blood is not made in the liver); that the kidneys separate the urine from the blood, which is passed by the ureters to the bladder and is discharged "in convenient time"; that the spleen takes away the earthy parts and dregs, and the gall-bladder "the superfluous gall"; that in the right ventricle the blood is "put in perfection," and by the veins the blood is sent to all the members; that every member takes the blood and "nourisheth itself from it in its own fashion"; that the left ventricle makes the blood so "subtile, that it is called spiritual, and sendeth it to all the members by its arteries, in order the other blood of the veins to warm and winnow"; that the heart distributes the best of the blood to the lungs by the pulmonary artery (the arterial vein); that out of the blood the animal spirits are made in the chorioid plexuses. (In the second passage quoted it is evident that by the "*rete mirabile*, which lieth beneath the ventricles of the brain," is meant the chorioid plexuses; Servetus speaks of the chorioid plexuses and of their producing the animal spiritus from the vital spiritus).

In brief, as regards the movements of the blood, Rabelais, in 1546, thought that the materials for the production of the blood were absorbed by the mesenteric veins from digested food and carried to the liver; that these matters were changed and made into blood in the liver; that the blood is brought to perfection in the right ventricle and is sent by the veins to all parts of the body for their nourishment; that the blood is subtilized in the left ventricle (in which part the vital spiritus is formed) and is sent by the arteries to "all the members" in order to warm and otherwise modify the blood sent to them by the veins; that the blood is sent to the lungs by the pulmonary artery; that the vital spiritus is changed into animal spiritus in the chorioid plexuses, by means of which (animal spiritus) the operations of the mind are conducted.

This was undoubtedly the condition of general knowledge of the movements of the blood up to the time of Harvey (1616). Vesalius, in 1543, three years before Rabelais, denied the existence of openings in the interventricular septum; but he made no notable physiological deductions from this most important anatomical observation. If this had been recognized in connection with the movements of the blood, knowing that the blood is carried to the lungs by the pulmonary artery, it would have been evident that the blood could reach the left side of the heart by no other way than by the pulmonary veins. Galen, in the second century, had shown that the arteries carried blood only and not air; which was well known to Rabelais and to some of the learned men of his time. As a matter of fact, the idea of the uses of the valves of the veins, which indicated the direction of the flow of blood in these vessels, was the idea which rendered it impossible to describe the movements of the heart and blood (*motus cordis et sanguinis*) in any other way than as was described by the immortal discoverer of the circulation. The correction of the ancient error which admitted openings in the interventricular septum made the passage of blood through the lungs a logical necessity; and the discovery of the valves of the veins made the general circulation an unavoidable logical sequence; yet the importance of the anatomical description of the heart by Vesalius was not thoroughly comprehended by investigators for seventy-three years (1543 to 1616); and the uses of the valves of the veins remained unknown for more than half a century.* The writings of Servetus had absolutely no influence on the discovery of the circulation; the physiological passages in the *Christianismi restitutio* were unknown until long after the

*The history of the discovery of the valves of the veins is somewhat obscure. The best information in regard to it is that Étienne described valves in branches of the portal vein in 1545; Lucitanus, in 1551, published a letter from Cannanus in which he described (probably in 1547) valves in certain veins; Eustachius described valves in the coronary vein in 1563, and Piccolomini published a clear account of the valves of the veins in 1586. Fabricius published accurate descriptions and delineations of the valves in 1603.

publication of the *Exercitatio anatomica de motu cordis et sanguinis*, in 1628.

Michael Servetus (Michael Seruetus, Miguel Serveto, Michael Villanovanus, or Miguel de Villeneuve) was born in Tutella, in Navarre, in 1511, and died in 1553. The history of Servetus, with his tragic death at the stake, is too well known to call for extended repetition here. He met Calvin in Paris in 1536 and had some discussion with him on theological questions concerning which Servetus had written in 1531 and 1532 (*De Trinitatis erroribus*). He corresponded with Calvin in 1545 and 1546. In January, 1553, he published the *Christianismi restitutio*, of which but two perfect copies are known to be in existence. This book earned for Servetus the relentless enmity of Calvin. In March, 1553, he was interrogated by the inquisitor-general at Lyons, having been arrested on the charge of heresy. Early in April he escaped from his prison. In August he was arrested in Geneva. On October 26th he was convicted and sentenced to be burned alive. The sentence was carried out October 27, 1553. It is said that copies of his book were burned at the same time.

The medical history of Servetus is important as bearing upon his authority as a scientific writer. It is recorded that he studied medicine in Paris, in 1536, under Günther, Dubois,* and Fernel. He succeeded the great anatomist Vesalius as assistant to Günther. Günther describes him as a man of high culture, specially skilled in dissection and with a profound knowledge of the works of Galen. In 1540 he entered the medical school at Montpellier. He acted as the private physician to Paulmier, archbishop of Vienna, from 1541 to 1553. He wrote a number of books on various subjects and among them a work containing six lectures on digestion and the composition and use of syrups. The first edition of this book was published in 1537, the fifth and last edition bearing the imprint: Venice, 1548. According to Alexander Gordon (*Encyclopædia Britannica*, Article, Servetus), "the passage describing the pulmonary circulation is first noticed by W. Wotton, in *Reflections upon Ancient and Modern Learning*, 1694."

I give here the original and a translation of the celebrated passage in the *Christianismi restitutio*. The original Latin was reprinted by Flourens and afterward by Milne Edwards.† I have never seen a complete trans-

*Dubois is known in literature as Jacobus Sylvius.

† In the *Encyclopædia Britannica*, Sir William Turner, the writer of the article *Anatomy*, reprints, in the original Latin, what purports to be the entire passage from Servetus. This reprint, however, is incomplete. Nearly one fourth of the passage—the last portion, which is important—is omitted. Also, there are many important variations from the text as given by Flourens and Milne Edwards. In addition, the extraordinary error is made of crediting the passage to a work, *De Trinitate* (probably *De Trinitatis erroribus*) instead of to the *Christianismi restitutio*. These errors may be due to the fact that there are but two copies of the *Christianismi restitutio* known to be in existence, one in the National Library in Paris and the other in the Imperial Library in Vienna. I have never seen it stated that a copy is to be found in the British Museum. There is said to be an imperfect copy in Edinburgh, partly reprinted.

lation into English. The translation here given I believe to be absolutely literal and accurate as regards anatomical terms. In its preparation I have been more than assisted by Mr. Montgomery Schuyler, an accomplished scholar and eminent littérateur, of New York:

"Vitalis spiritus in sinistro cordis ventriculo suam originem habet, juvantibus maximè pulmonibus ad ipsius generationem. Est spiritus tenuis, caloris vi elaboratus, flavo colore, ignea potentia, ut sit quasi ex puriori sanguinis lucidus vapor, substantiam in se continens aquæ, aeris et ignis. Generata ex facta in pulmonibus mixtione inspirati aeris cum elaborato subtili sanguine, quem dexter ventriculus cordis sinistro communicat. Fit autem communicatio hæc, non per parietem cordis medium, ut vulgo creditur, sed magno artificio à dextero cordis ventriculo, longo per pulmones ductu, agitatur sanguis subtilis: à pulmonibus præparatur, flavus efficitur, et à vena arteriosa in arteriam venosam transfunditur. Deinde in ipsa arteria venosa inspirato aeri miscetur et expiratione à fulgine repurgatur. Atque ità tandem à sinistro cordis ventriculo totum mixtum attrahitur, apta supellex, ut fiat spiritus vitalis.

"Quòd ità per pulmones fiat communicatio et præparatio, docet conjunctio varia et communicatio venæ arteriosæ cum arteria venosa in pulmonibus. Confirmat hoc magnitudo insignis venæ arteriosæ, quæ nec talis, nec tanta facta esset, nec tam à cordæ ipso vim purissimi sanguinis in pulmones emitteret, ob solum eorum nutrimentum, nec cor pulmonibus hac ratione serviret; cum præsertim antè in embryone solerent pulmones ipsi alimèdè nutrirì, ob membranulas illas, seu valvulas cordis, usque ad horam nativitatì nondum operatas, ut docet Galenus. Ergò ad alium usum effunditur sanguis à corde in pulmones hora ipsa nativitatì, et tam copiosus. Item, à pulmonibus ad cor non simplex aer, sed mixtus sanguine mittitur per arteriam venosam: ergò in pulmonibus fit mixtio. Flavus ille color à pulmonibus datur sanguini spirituosus, non à corde. In sinistro ventriculo non est locus capax tantæ et tam copiosæ mixtionis, nec ad flavum elaboratio illa sufficiens. Demum, paries ille medius, cum sit vasorum et facultatum expers, non est aptus ad communicationem et elaborationem illam, licet aliquid resudare possit. Eodem artificio, quo in hepate fit transfusio à vena porta ad venam cavam propter sanguinem, fit etiam

"The vital spiritus has its origin in the left ventricle of the heart, the lungs in the greatest degree aiding its generation. This spiritus is attenuated, elaborated by force of heat, of yellow color, of fiery power, so that it is, as it were, a clear vapor from the purer blood, containing in itself the essence of water, air, and fire. It is generated from an admixture made in the lungs of inspired air with elaborated subtile blood, which the right ventricle of the heart communicates to the left. Indeed this communication is not made through the middle wall of the heart, as is commonly believed, but by great ingenuity from the right ventricle of the heart, by a long passage carried through the lungs, the subtile blood is put in motion: it is prepared by the lungs, is made yellow, and is transfused from the vena arteriosa to the arteria venosa. Thereupon, in the arteria venosa itself, it is mixed with the inspired air and by expiration is purged of its dark substance. Also in this wise at last from the left ventricle of the heart the whole admixture is drawn, material is adapted, so that it makes vital spiritus.

"Since the communication and preparation is thus made through the lungs, it teaches a manifold conjunction and communication of the vena arteriosa with the arteria venosa in the lungs. The remarkable magnitude of the vena arteriosa confirms this, which would be made neither such, nor so great, nor would it thus send out from the heart itself a force of the purest blood into the lungs, for the purpose of their nourishment alone, nor would the heart for this purpose supply the lungs; especially since previously in the embryon the lungs themselves were accustomed otherwise to be nourished, on account of these little membranes, or valvules of the heart, not yet opened even to the hour of birth, as Galen teaches. Therefore for another purpose, the blood is poured out from the heart into the lungs at the very hour of birth, and in such abundance. Likewise, air not simple, but mixed with blood, is sent to the heart from the lungs through the arteria venosa: therefore the mixture is made in the lungs. This yellow color is given to the sanguis spirituosus by the lungs,

pulmone transfusio à vena arteriosa ad arteriam venosam propter spiritum. Si quis hac conferat cum iis quæ scribit Galenus, lib. vi et vii, *De usu partium*, veritatem penitus intelliget, ab ipso Galeno non animadversam. Ille itaque spiritus vitalis à sinistro cordis ventriculo in arteriis totius corporis deinde transfunditur, ità ut qui tenuior est superiora petat, ubi magis adhuc elaboratur, præcipuè in flexu retiformi, sub basi cerebri sito, in quo ex vitali fieri incipit animalis, ad propriam rationalis animæ sedem accedens. Iterum ille fortius mentis ignea vi tenuatur, elaboratur, et perficitur, in tenuissimis vasis seu capillaribus arteriis, quæ in plexibus choroidibus sitæ sunt, et ipsissimam mentem continent. Ili plexus intima omnia cerebri penetrant, et cerebri ventriculos internè succingunt, vasa illa secum complicata et contexta servant, usque ad nervorum origines, ut in eos sentiendi et movendi facultas inducatur.

"Vasa illa miraculo magno tenuissime contexta, tametsi arteriæ dicantur, sunt tamen fines arteriarum, tendentes ad originem nervorum, ministerio meningum. Est novum quoddam genus vasorum. Nam, sicut in transfusio à venis in arterias est in pulmone novum genus vasorum, ex vena et arteria, ità in transfusione ab arteriis in nervos est novum quoddam genus vasorum, ex arteriæ tunica et meninge: cum præsertim meninges ipsæ suas in nervis tunicas servant."

Milne Edwards, *Leçons sur la physiologie*. Paris, 1858, tome III, p. 17.

not by the heart. In the left ventricle there is no capacious place for so great and such copious admixture, nor is there elaboration sufficient for the yellow. Indeed, that middle wall, since it lacks vessels and facilities, is not adapted to communication and that elaboration, even if it could exude anything. By the same arrangement by which transfusion is made in the liver from the vena porta to the vena cava through blood, a transfusion is also made in the lung from the vena arteriosa to the arteria venosa through spiritus. If one will compare this with that which Galen writes, lib. vi et vii, *De usu partium*, he will thoroughly understand the truth not observed by Galen himself. This vital spiritus accordingly is transfused from the left ventricle of the heart and then into the arteries of the whole body, so that what is of greater tenuity seeks the superior, where it is still more elaborated, especially in the flexus (plexus) retiformis, situated under the base of the brain, in which from the vital begins to be made the animal, approaching to the proper seat of the rational soul. Again, this is more strongly attenuated, elaborated, and perfected by the fiery power of the mind, in the thinnest vessels or capillary arteries, which are situated in the chorioid plexuses, and contain the very mind itself. These plexuses penetrate all intimate parts of the brain, and gird from below inwardly the ventricles of the brain, preserving these vessels complicated and entwined with each other, as far as the origins of the nerves, in order that the faculty of feeling and of moving may be imparted to them.

"These vessels most delicately in a very miraculous manner interlaced, although they are called arteries, are nevertheless the ends of arteries extending to the origin of nerves, for the service of the meninges. It is a certain new kind of vessels. For, as in transfusion from veins to arteries there is in the lung a new kind of vessels out of vein and artery, thus in transfusion from arteries to nerves there is a certain new kind of vessels, out of the tunic of the artery and the meninx: especially as since the meninges themselves preserve their own tunics in the nerves."

In the first sentence of the extract from Servetus, he says, like Rabelais, that "the vital spiritus has its origin in the left ventricle"; Rabelais says that the left ventricle makes the blood so subtile that it (the blood) is called spiritual and the left ventricle sends it to all the mem-

bers by the arteries to warm and "winnow" the blood of the veins. Servetus says that the lungs "in the greatest degree" aid in the generation of the vital spiritus; that it (the vital spiritus) is attenuated and elaborated by force of heat, is of a yellow color (*flavo colore*) and of fiery power, and is, "as it were, a clear vapor," containing the essential parts of water, air and fire.* "It (the vapor) is generated from an admixture, made in the lungs, of inspired air with elaborated subtile blood, which the right ventricle of the heart communicates to the left." This communication is not made through the middle wall of the heart, as is commonly believed, but from the right ventricle, "by a long passage carried through the lungs, the subtile blood is put in motion." It is prepared by the lungs, is made yellow and is passed from the pulmonary artery to the pulmonary vein.† The blood is mixed with the inspired air in the pulmonary artery "and by expiration is purged of its dark substance." In this wise the whole admixture is drawn from the left ventricle, "material is adapted, so that it makes vital spiritus."

Here is a description of the passage of dark blood through the lungs, from the right to the left side of the heart. In the lungs the blood is purged of "dark substance," which is thrown off in expiration, and is changed into vital spiritus, described as a clear vapor, of yellow color. This is the idea of the pulmonary circulation given by Servetus.

Rabelais thought that the blood was made so subtile in the left ventricle that it was called spiritual and was sent by the left ventricle to the parts to "warm and winnow" the venous blood; which latter was also sent to the parts for their nourishment, but by the right ventricle. Rabelais also spoke of the heart as distributing its best blood to the lungs by the pulmonary artery. He indeed came very near a description of the passage of blood through the lungs; and he actually did say that spiritual blood was sent by the left ventricle through the arteries "to all the members."

The arguments of Servetus to sustain his theory of the passage of blood through the lungs are most interesting. He says that since the communication and preparation of the vital spiritus is thus made through the lungs, there is a manifold conjunction and communication in the lungs of the pulmonary artery with the pulmonary vein; and that this is confirmed by the great size of the pulmonary artery, this vessel carrying too much blood to the lungs simply for their nourishment. He speaks of the lungs of the fœtus as "accustomed otherwise to be nourished," on account of valvules of the heart "not yet

opened even to the hour of birth, as Galen teaches"; "the blood is poured out from the heart into the lungs at the very hour of birth, and in such abundance; the yellow color is given to the *sanguis spirituosus* by the lungs, not by the heart; the left ventricle is not sufficiently capacious for so great an admixture of air with the blood; the arrangement for the passage of blood in the lungs from the pulmonary artery to the pulmonary vein is the same as for the passage of blood in the liver from the vena porta to the vena cava. Indeed, in his argument, Servetus quite closely describes the changes in the pulmonary circulation which take place at birth.

It is not germane to my purpose to follow either Servetus or Rabelais through their speculations in regard to the generation of animal spiritus from vital spiritus. Servetus speaks of the animal spiritus as elaborated and perfected in the flexus retiformis under the base of the brain and as still more strongly attenuated, elaborated and perfected in the chorioid plexuses, describing the tunics of the vessels of these plexuses as uniting with the meninges to form nerves. Rabelais speaks of the animal spirits as made in the *rete mirabile* out of the spiritual blood: "The philosophers and physicians affirm that the animal spirits spring from, have their origin in, and operate through the arterial blood purified and refined to perfection within the *rete mirabile*, which lieth beneath the ventricles of the brain."

One can hardly study closely the passages quoted from Rabelais without appreciating how near philosophers and physicians in the middle of the sixteenth century were to a knowledge of the pulmonary circulation. As regards the systemic circulation, the notion seems to have been that blood was made in the liver out of nutritive matters of food absorbed by the mesenteric veins, was transported to the heart to be further refined, and was sent to the parts by the veins; that the left ventricle sent arterial blood to the parts for some indefinite purpose. It remained to show that the blood could move in the veins in only one direction and could not pass from the right ventricle to the periphery, to give the key to knowledge of the general circulation. This was done when the great anatomist, Fabricius, demonstrated the valves in the veins to the great physiologist and philosopher, the immortal Harvey.

The work of Servetus was not a factor in the discovery of the circulation, because it was unknown, it is said, until 1694. It might be said that the cruel burning of Servetus and the practical destruction of his work, in 1553, delayed the discovery of the circulation for more than half a century; but the history of physiology shows that Realdus Columbus, of Cremona, a disciple of Vesalius, wrote, in 1559, that blood did not pass through the interventricular septum, but was carried from the right ventricle to the lungs by the pulmonary artery and then passed with air into the left ventricle by the pulmonary vein. Cæsalpinus, in 1583, wrote that the veins carried nutritive matters to the heart and that the arter-

*Further on, Servetus calls this "*sanguis spirituosus*."

†At the time of Rabelais and Servetus the general notion was that there was but one pulmonary vein. Eustachius made his celebrated *Anatomical Engravings* in 1552; but he was unable to publish them, and they were practically buried in the papal library until 1714, when they were made public by Lancisi. In *Tab. XXVII, Fig. 13* is a very exact representation of the four pulmonary veins. (Sprenzel, *Histoire de la médecine*, Paris, 1815, tome IV, p. 35.)

ies distributed these matters to the parts. He noted that when a vein was ligated, the vessel became swollen below and never above the point of ligation. He also wrote that the blood *circulated* in the lungs to pass from the right to the left side of the heart; but he had a vague idea only of the general circulation and adhered to the ancient error that there were openings in the interventricular septum through which the blood passed freely between the two sides of the heart.* How far, then, a general knowledge of the description of the pulmonary circulation by Servetus would have hastened the discovery of the general circulation, if at all, it is impossible to determine.

The idea of this article suggested itself to me in reading the passage that I have quoted from Rabelais. After much study and bibliographical research, I have attempted to give an idea of the progress of actual knowledge in regard to the movements of the blood, up to the grand epoch in physiology marked by Harvey, and especially the knowledge that prevailed in the middle of the sixteenth century.

NOTES ON RINGWORM.

By A. RAVOGLI, M. D.,

CINCINNATI.

TINEA TONSURANS, herpes tonsurans, trichophyties, in one word ringworm, comprehends several affections of the epidermis and its appendages, hair and nails, which recognize as their cause the presence of a parasite known under the name of trichophyton. A few years ago it was believed that trichophyton was only one kind of parasite, the one and the same which in 1844 had been discovered and described by Malmsten. But since the patient and classic studies made by Sabouraud on this subject we have been compelled to change our views somewhat.

The question of the plurality of the trichophytions has been reviewed in a masterly manner by Malcolm Morris in his interesting work, *Ringworm and the Trichophytions*, from which I take a few points.

In 1891 Furthmann and Neebe† maintained the plurality of the fungus in the ringworms, but the new positive observations begin with the researches of M. Sabouraud,‡ who, in 1892, gave his first account to the scientific world of the results obtained, and in 1894 gave the final report in his work, *Les Trichophyties humaines*.

His conclusions are that, under the name of tinea tonsurans trichophytina, have been confounded two diseases which, although they have some similarity of appearance, yet are different on account of the different parasite from which they are derived. According to Sabouraud, one kind of affection is the result of a parasite which was discovered by Gruby over fifty years ago and named *Microsporon Audouini*. This causes the kind of ringworm most contagious and most refractory to treatment, which

is often seen in the schools in France. The microscopical characteristics are the smallness of the spores of the parasite, and the clinical are that it is limited to children and attacks the scalp only. The other disease is caused by the real trichophyton, which shows large spores. Sabouraud divided them into two groups, according to the location of their spores inside or outside of the hair, calling the first endothrix, and the second ectothrix. The former attack principally the scalp, and only at times the hairless parts, tinea circinata; the latter attack the skin, occasionally the scalp in children, and are nearly the sole cause of ringworm of the beard. The endothrix is spread from man to man; the ectothrix is the result of a direct inoculation from animals, such as the horse, the cat, etc. Of both these varieties of large-spored fungus there are numerous species, and Sabouraud explains the polymorphism of ringworm by the multiplicity of the species. They have one objective characteristic in common, namely, the circinate outline of the epidermic lesions.

Benignity is a distinguishing feature of trichophytic ringworm of animal origin. Sometimes it lasts two or three months, sometimes longer. Suppurative lesions, kerion, and sycosis are caused by a special ectothrix fungus derived from the horse.

The cultures of the small-spored fungus have always the same characters, but those of the large trichophytic fungi differ among themselves. When taken, however, from the same case, they are always reproduced the same.

Bodin, studying the ringworm fungi which infest the horse, pointed out the habitat of the trichophyton, which, as in man, is circumpilar and intrapilar. The trichophytions of the horse, from the manner of their fructification, are divided into two groups, of which one has the ordinary conidia in bunches, and the other which he calls faviform, on account of the resemblance to favus. He thinks, therefore, that there are diseases in man and in animals resulting from fungi which cannot be clinically distinguished, but mycologically are somewhat allied to the achorion; as a consequence he thinks it impossible at present to draw a line of distinction between trichophytosis and favus.

Leslie Roberts does not believe much in the morphological and in the cultural test, but he thinks that the criterion by which to distinguish the trichophytic fungus is the degree of power to digest horny tissues. He thinks that light hair, on account of lack of pigment, is more susceptible to attacks by ringworm than dark-pigmented hair. He makes two varieties of fungi, one kind which digests both the cuticle and cortical substance of the hair, and a variety that digests the cortical substance first, leaving the cuticle unaffected. He does not, however, accept Sabouraud's doctrine that tinea tonsurans is a disease of two definite types, produced by distinct classes of fungi. In the same way Rosembach, Mibelli, and Charles J. White have all referred to different kinds of trichophyton, which, however, seem to be only varieties.

*Milne Edwards, *op. cit.*, tome III, p. 19.

†*Monatshefte für praktische Dermatologie*, 1891.

‡*Annales de dermatologie*, 1892.

Kroesing* opposed the distinction of ringworm fungi into small- and large-spored, maintaining that the size of the spores was variable in the same fungus and in the same culture. Clinically, he maintains that the same fungus may cause deep and superficial lesions, sycosis, and tinea circinata, and that it is impossible to diagnose what fungus has caused a case of ringworm.

Moulds belonging to the class of the *Mucedineæ* form a large group of natural families. Among them is the *Sporotrichum Botrytis* (Link and Lanardo). The character of these moulds is to have their spores external, pediculated in bunches on their hyphus. The trichophytons belong to this family of sporotrichum, which in their parasitic vegetative life show mycelium filaments and endospores in a chain, and when cultivated show large external spores in bunches, as can be seen from Fig. 1.

For many years it has been maintained that the species of the groups of the *Mucedineæ* in certain favorable conditions can produce fungi of a kind superior to those from which they had their origin. Sabouraud showed many cultures of the non-parasitic sporotrichum which, on account of the different culture media, showed forms similar to the *Sporotrichum nellericum*, and this last in other cultures took on a dry, granular appearance as a form of chetomium. If these changes take place in the non-parasitic sporotrichum, it is quite reasonable to admit that the parasitic sporotrichum (trichophyton) can change in appearance according to the different culture media and to the physicochemical conditions. The more or less azotized properties of the culture medium, the degree of temperature to which the culture is exposed, and also the way the culture tube is closed may have some influence on the growth of the parasite. In fact, in these cultures you will find a great difference of appearance; in the young cultures you see the parasite growing in the form of small granules, recalling the structure of the ringworm of the skin, in the old cultures you see a mouldy appearance of the whole culture. In the centre you see tufts of a new and different parasitic vegetation which have no resemblance to the first young culture from which it took its origin.

From these observations the school of Prague came to the conclusion that there was only one trichophyton indefinitely multiform. This assertion has been strongly opposed by Sabouraud, who maintains that there are nearly twenty species of trichophytons which have always maintained their individuality. Of course we must have the greatest regard for the assertions of so distinguished a mycologist, who has given the most complete study to this subject; but from the clinical standpoint I must say that these distinctions are not of much interest, as I have seen in all my examinations the same trichophyton consisting of mycelium and spores producing different morbid phenomena. In my cultures I have found that the parasite taken from the hair or from the scales has always

produced in the end the same mouldy white appearance, such as you see in these cultures which I show to you.

From the illustration you can see that the fungus results from long cells connected together end to end, forming a kind of tubes ramified together; this forms the vegetative part of the fungus (Fig. 1), the so-called thallus, or mycelium. The round cells are the fructifying element of the fungus, the so-called spores, or conidia, which are the essential part for distinguishing the fungi. The spores are the fruit and the seed, which, falling on the skin or on a substance capable of giving them nutrition, develop mycelium and reproduce the fungus. On account of the way the spores are grouped and disposed in the organ of fructification, the fungi are distinguished into *penicillium*, in which the spores are disposed in the form of a brush, *mucor*, in which the spores are inclosed in a kind of capsule, and *aspergillus*, in which the sporangia are round, in globular form.

In the *Mucedineæ* the reproduction takes place oftenest by conidia, which are groups of cells growing directly from the tubes of the mycelium, without a definite organ of fructification. This you find to be the fact with the trichophyton, which is the subject of our study.

It is scarcely necessary to say that in 1860 Lowe tried to demonstrate that the trichophytons were the result of a modification of favus (*Achorion Schoenleinii*) and that both took their origin from a kind of aspergillus. Hebra, in 1854, was rather inclined to believe the possibility of the same origin of both fungi. He experimented with the application of the powdered crusts of favus on a wet cloth to the skin, which resulted in the production of rings apparently from trichophyton. Furthermore, the discovery made by Tulasne of the polymorphism of the fungi seemed to support this theory. From my observations I can state, as all dermatologists agree, that achorion, trichophyton, and microsporon are three distinct forms of *Hyphomycetes*, and there is no common origin among them. I make this statement for the reason that to-day some still insist on the possibility of some similarity between favus and ringworm, and Bodin asserts that it is hard to distinguish to what class some peculiar forms must be referred.

The anatomical tissues attacked by the dermatophytes are the epidermis, the hair, and the nails, on which they have a peculiar digestive property; they penetrate into them, making those tissues their habitat. They detach the epidermic cells from one another, and, by digesting the hard membrane, appropriate their elements as nutrition for the fungus. The fungus in the epidermis either by its presence causes mechanical irritation or by its chemical products produces an inflammatory process which is revealed by redness, scaliness, vesicles, pustules, and at times abscesses, as a result of their presence.

The affections resulting from the presence of the fungus in the epidermis have naturally a chronic evolution, as it is entirely subordinate to the vegetative power of the fungus, and it is only when a treatment succeeds in de-

*Archiv für Dermatologie und Syphilis.

Fig. 1.

Fig. 2.

stroying its vegetative power or removing the fungus itself that we obtain recovery from the dermatomycoses.

These affections are carried from man to man or from lower animals to man. Trichophytons are widespread among horses, cats, dogs, and also fowls. These fungi have different forms when cultivated from the different animals, but when inoculated on man they have the same effects, the same appearance, and when cultivated again from man they give as a final result this white mould which you see vegetating in these bottles.

Sabouraud laid great stress on a distinction of the trichophytons as ectothrix, endothrix, and endoectothrix, the first vegetating outside of the hair, on the epidermis, in patches, the second vegetating in the hair, the third vegetating either in the hair or outside. I beg to call your attention to our microphotograph (Fig. 2.) where you can see a quantity of spores on some filaments of mycelium, vegetating outside of the hair, and groups of spores vegetating and disposed in lines between the fibres of the hair. You can easily be persuaded that there is no

Fig. 3.

difference between them, and that the same fungus vegetates in the fibres of the hair and in the scales of the epidermis. Furthermore, in a large number of cases in which the hair has been affected the epidermis had been affected first and then it spread to the hair. Of these two cultures, which look exactly alike, one is the result of the inoculation of an epidermic scale from a ringworm patch, and the other from a hair taken from another patient. For these reasons, although I admire the studies of Sabouraud, and I consider his classification highly scientific, yet I consider it of not much interest clinically, when I find that the same identical fungus vegetates inside of the hair and in the epidermis as endothrix and ectothrix.

What I wish the student to be able to establish without hesitation is the diagnosis of ringworm, which he can easily do from the clinical characters, a scaly patch in a circular form with stumps of broken hair, and from the positive observation by finding the fungus in the scales or in the hair. Kaposi* expresses his opinion by saying that all the different forms of herpes tonsurans which he points out are only varieties of the same disease on account of the different anatomical regions or simple complications due to the same identical fungus, trichophyton.

The difference in the appearance of the eruption of the hairy scalp and of the skin without hair is to be found in the peculiarity that the fungus vegetates in the hair follicles. This causes the obstinacy of the disease, because the fungus growing in the follicles is concealed and protected from the action of the remedies applied. The same condition occurs in the cases of herpes tonsurans of the back of the hands, where the small red points are the opening of the hair follicles invaded by the fungus.

Fig. 4

Herpes tonsurans sometimes spreads to a great extension; at other times it remains circumscribed to a certain area, without growing, for years, but I have seen it in some cases invade the whole scalp. Subjective symptoms are limited to a moderate pruritus. The disease remains limited to the epidermis and in consequence does not

produce deep alterations in the tissues of the skin, and so leaves no scar or permanent alopecia.

On the general surface of the skin herpes tonsurans shows itself in the form of red spots or scaly round patches or vesicles, and also bullæ. From the occurrence of these lesions it has taken the names of herpes tonsurans maculosus, squamosus, vesiculosus, and bullosus. In these cases the eruption has a tendency to an acute course, showing the irritating qualities of the fungus capable of producing inflammation and pus formation.

Concerning the treatment, this consists in the local application of almost any substance capable of producing the casting off of the epidermis. Tincture of iodine, a mixture containing chysarobin or resorcin, or pyrogallic acid, etc., a solution of bichloride of mercury, all have given good results. When the epidermis is removed by inducing desquamation, the parasite goes off together with the necrosed epidermic scales, and it is not difficult to get rid of it. The difficulty is when it has affected the hair and the hair follicles, where the fungus finds itself protected, and in these cases we must resort to epilation, so that removing the hair we also remove the parasitic elements. The old Wilkinson's ointment modified by Hebra has always given in my hands very gratifying results in nearly all forms of trichophyties. For cases of tinea trichophytina of the scalp a mixture of crude coal oil and olive oil has been rubbed daily on the scalp of the children by means of a strong painting brush. This application is sometimes the cause of pustulation of the scalp, which is rather beneficial, causing the destruction of the parasitic elements in the hair follicles. I must mention a method which I have used for several years in obstinate cases, which was at first proposed by H. J. Reynolds, of Chicago, at the International Medical Congress at Washington. It consists in utilizing the continuous electric current running from the positive to the negative pole so as to introduce the remedy into the follicles of the hair. When a sponge impregnated with an antiparasitic solution is attached to the positive pole and applied on the diseased patch, and the negative is applied at some distance, the fluid will penetrate much more deeply into the tissues than it would without the help of the electric current. A one-per-cent. solution of bichloride of mercury is the ordinary antiparasitic liquid which I use, but other solutions can also be used. The duration of the application will not exceed thirty minutes, and it can be made once a day. I have used these applications in cases of tinea tonsurans of the scalp and also of the body, and I have always obtained gratifying results. This method has been also employed by E. Charon* in his clinic in Brussels.

In regard to prophylaxis, it is necessary to call attention to the contagiousness and to the frequency of this disease. In my twenty years of practice in Cincinnati I have met with only three cases of favus, showing that this

*Pathology and Treatment of the Diseases of the Skin.

*Western Medical Reporter, February, 1888.

disease, on account of the sanitary regulations for immigrants, has a tendency to disappear. Trichophyties, however, is spreading, on account of its contagiousness. In fact, the scales of the epidermis containing parasitic elements are continuously cast off, and when placed on the skin or on the scalp they are reproduced. It seems to me that for the reproduction of tinea tonsurans there is always required a direct contact of the different wearing apparel or utensils. In families in poor circumstances, in which several children are placed together in the same bed, we find that nearly all are affected with this disease. In the same way, by using towels, combs, and brushes the disease is easily spread. In the City Hospital, in Ward B, I have constantly from three to six cases of tinea tonsurans capillitii in children for treatment which are sent from the Children's Home. They are kept together with other children convalescent from other diseases, and in many years I have never seen a case of tinea tonsurans inoculated in the ward. The nurses are very careful to keep separate the towels and the other articles of the little patients with tinea tonsurans, and after they have been cleaned and dressed they wear a cap, which they cannot remove. The rapid spreading of tinea tonsurans can be easily checked by the antiseptic rules used in dressing and treating children.

The *chronic* character of the disease and the long time which is required for the treatment of tinea tonsurans of the scalp are points against keeping children out of school. Furthermore, the parents, on account of the little or no complaint of the children, do not give any attention to their treatment, leaving the disease alone. In the same way children which we have discharged from the hospital as cured, after a few months have been brought back with the scalp covered again with new patches of tinea tonsurans. The relapse could have been easily avoided by some cleanliness and by rubbing the scalp once a day with an antiseptic solution. I think, therefore, that it is a great mistake in public hygiene to order children affected with tinea tonsurans out of school and allow them to go around in the streets. On the contrary, they ought to be sent to school, where they should be kept in a separate room for children affected with tinea tonsurans. The teacher ought to be trained in the treatment of this disease, and the children ought to be treated every day according to the directions of the physician.

Another place where the disease is freely spread among grown persons is the barber's shop. The use of the same utensils for all the customers is dangerous and likely to cause infection with the trichophyton. Barbers ought to be compelled to have a basin of boiling water in which to plunge their razors, brushes, and combs after having attended to a customer. The utensils ought to be metallic, with metallic handles, so that they can be boiled without spoiling them.

Everybody ought to be cautioned not to use combs and brushes hanging in public places, in the railroad cars,

etc., but carry in his pocket a small comb, avoiding in this way the use of the comb used by others.

The roller towels in public offices, factories, etc., where everybody wipes his or her hands and face, are also dangerous for the spreading of the ringworm. In the same way patients affected with herpes tonsurans of some part of the face very often infect the whole face, scalp, and neck by rubbing their face with the towel after washing, spreading the scales and the crusts filled with spores to other places which had not before been affected. It is necessary, therefore, to caution our patients not to rub when wiping their face affected with this disease, in order to prevent further spreading of the affection.

In conclusion, I can say that with some attention and with some care tinea tonsurans can be easily diminished and prevented from spreading.

HYPERACIDITY
(SUPERACIDITY, HYPERCHLORHYDRIA,
SUPERACIDITAS CHLORHYDRICA);
A CLINICAL STUDY.

By H. ILLOWAY, M. D.,

NEW YORK,

FORMERLY PROFESSOR OF DISEASES OF CHILDREN, CINCINNATI
COLLEGE OF MEDICINE AND SURGERY; FORMERLY VISITING
PHYSICIAN TO THE JEWISH HOSPITAL, CINCINNATI;
FELLOW OF THE NEW YORK ACADEMY OF
MEDICINE, ETC.

(*Concluded from page 1034.*)

As illustrative of what has been set forth, the following histories of a few of the cases are appended.

CASE I.—June 22, 1895. Miss B. E., American, æt. thirty-seven (but does not look a day over twenty-five; I was greatly surprised when she told me her age); five feet four inches tall; weight, from 120 to 125 pounds; organist; she also assists her mother, who keeps a boarding house, with her household work. She says that she is very nervous; that her mother also is a very nervous woman; that it is not a matter of inheritance with either of them (as they were never nervous in the days of their prosperity), but that they were made so by the cares and vicissitudes of their life (after the loss of their fortune). Formerly she was much troubled with chills, and shivers running through her body. Her hands would suddenly become very cold. Of late this has not been so frequent or so marked. Her general health (except as to dysmenorrhœa and the trifling complaint above mentioned) had always been good up to four years ago. At that time her stomach began to trouble her and has continued to do so, more or less, ever since. She complains of indigestion. It seems to her as if her food remained long in her stomach; she has a sense of fulness in her throat, as if some foreign body were lodged there; at times it seems as if it were a ball. Occasionally she has a pain that shoots from her stomach to her left ear. What distresses her most now is a *burning in her stomach*. She takes much sodium bicarbonate to relieve this. Her bowels are regular. She does not sleep well; she rarely sleeps the night through; most frequently she will wake

out of her first sleep and remain awake for two or three hours, then sleep by cat-naps until it is time to rise. She has been under treatment with a number of physicians, and has taken all sorts of remedies—alkalies, acids, biters, etc., and has been dieted in various ways.

Examination.—Teeth good. Tongue clean. She is in fair flesh. Stomach normally located. No splashing. Liver and spleen normal.

Stomach Chemismus.—Test breakfast, Ewald and Boas. Reaction to blue litmus +; reaction to Congo + (strong, characteristic); reaction to resorcin (Boas) + (strong). Total acidity, 72. Rennet +; pepsin +.

Diagnosis.—Hyperacidity, of nervous origin.

Treatment.—Dietary rules as already stated. To eat full meals; a good breakfast, a good lunch, and a regular dinner. Eggs, hard boiled, cold, and meats to constitute the main element of the various meals. To take a meat sandwich or a cup of milk with a cracker before retiring for the night.

Medication.—Vichy (French), half a glass t. i. d.; Fowler's solution, two drops, three times a day.

Other Measures.—A cold, moist compress* over the stomach at night.

July 2d.—She is feeling much better. The burning is very much ameliorated, and all the other symptoms have entirely disappeared. She has a good appetite, and enjoys her meals very much. As she has taken a bottle of Vichy daily for the last five or six days, I asked her to reduce the quantity to what I had advised her, namely, half a glass three times a day.

She was under treatment but a very short time. A few months later—early in the fall—I met her physician, who had referred her to me, and was then informed that Miss E. was completely cured of her stomach trouble.

CASE II.—Nov. 3, 1898. L. D., æt. thirty-four; height, five feet three inches; weight, 115 pounds (never weighed more when at his best than 123 pounds); married; one child; travelling salesman; smokes and drinks (both in moderation, he says). He has been troubled with his stomach for the last ten years. He gets a pain in his stomach which travels upward under his sternum. It comes on mainly about 5 P. M. Very frequently he also gets a pain in the morning about 10 or 10:30. The morning pain, he says, is different in character from that of the afternoon. It begins higher up under the sternum, about at the third intercostal space, and is a shooting pain. It does not interfere with his walking, does not compel him to stop if it happens to come on while he is walking, though on the whole he does not feel very much like moving about when he has the pain. He prefers to sit quiet. The afternoon pain is a "dull, dead pain." The pain is never felt in the back. It is always relieved by the ingestion of food. Sometimes the pain is attended with pyrosis. Occasionally, about once a month, he has seen the fluid thus discharged flecked with blood. He has never had a hæmorrhage. He has been under treatment with eminent men, has taken much medicine, has been dieted much, but has not as yet found relief.

His bowels were regular up to within a month. Since then he has been constipated. The stools were, as a rule, formed. His appetite is poor, and he eats very little. Sleeps well.

Examination.—The face is drawn somewhat; it has an expression of suffering. Teeth good. Tongue clean. No tenderness in the epigastrium; none in the abdomen.

No pressure spots (*Druckpunkte*). Stomach normally located. Tone of gastric muscle good.

Examination of Stomach Chemismus.—Test breakfast, Ewald and Boas. Strong characteristic responses to tests for hydrochloric acid. Total acidity, 87. Rennet (Boas) 1 to 30, rapid reaction; pepsin + (rapid digestion).

Diagnosis.—Hyperacidity.

Treatment.—On the lines laid down. For the pain I prescribed:

R Tincture of aconite root..... 6 drops;
Tincture of belladonna.....25 "
Distilled water..... 2 ounces.

M. Sig.—Take a teaspoonful on arising in the morning, and follow with a second dose in half an hour; then no more for that day.

Vichy, half a glass in the morning. In the afternoon, half an hour before the setting in of the pain, sodium bicarbonate. For the constipation, massage, etc.

November 10th.—Has had no pain for the last two days. Feels good; can eat well and enjoys his food. Weight, 118 pounds. Continue on as before directed. Take a third dose of the aconite and belladonna mixture at the same interval.

20th.—No pain since the last record. Bowels regular. Complains that his bladder is weak, that he cannot hold his water. Stopped the aconite and belladonna mixture. Gave him some tablets of strychnine sulphate, $\frac{1}{100}$ th of a grain each; to take four a day.

Dec. 18th.—He is well. He says he has gained two inches in his girth and an inch and a half in his chest measure.

Discharged from treatment.

I saw him in 1900, and he then informed me that he had not been troubled with his stomach, though he had, some months before, resumed smoking (in moderation) and taken a drink as before.

CASE III.—February 5, 1899. S. W., æt. thirty-five, a merchant, residing in a far Western city; height, five feet eight inches; weight, 125 pounds; single. Drinks three or four whiskeys a day, occasionally more. Smokes between five and ten cigars a day. He has had trouble with his stomach for many years, and has had many physicians without benefit. He complains of a "cramp or dry pain" in his stomach, which may or may not be followed by diarrhœa. He is very much worse in summer; then the cramp seizures are more violent, more frequent, and more often followed by diarrhœa. (In winter he may go two or three weeks without a seizure; in summer he has one or more every week.) Occasionally pyrosis. Appetite never anything to boast of. Last month he had no taste for food at all. Bowels (in the intervals between diarrhœal attacks) regular, open daily. Sleeps well.

Examination.—Teeth good. Tongue coated with a light white fur. From the ensiform cartilage to the umbilicus, 13½ centimetres. At 7 centimetres from the ensiform cartilage (downward) there is in the median line a very tender spot. In fact, the whole epigastrium is somewhat tender to percussion. The pain is always located in the epigastrium, 6 centimetres above the umbilicus. It is never around the navel. Otherwise, there is nothing abnormal either to inspection or palpation. Stomach normally located. No splashing. Water, 8 ounces. No splashing (even with the knees drawn up and the mouth slightly open). Liver and spleen normal.

March 5th.—Test breakfast, Ewald and Boas, one

*As to this, see Illoway, *Constipation in Adults and Children*, etc.

hour. Removed 85 cubic centimetres of stomach contents. On standing, it separated into two layers, water at top, bread at bottom. The latter, again, divisible into two layers; the upper and larger finely ground up, more like a very fine powder; the lower, coarser, like fine grits. The appearance of the whole, as ordinarily.

Reactions to tests for hydrochloric acid, strong, characteristic, rapid. Total acidity, 94. *Rennet* (Leo) +, thirteen minutes. Twenty centimetres milk, reaction in less than twenty-five minutes. *Pepsin* (hard-boiled white of egg) +.

Diagnosis: Hyperacidity.—More than probably there is a chronic congestion of the gastric mucous membrane, perhaps a subacute inflammatory condition of mild type, present. This latter would account for the marked anorexia.

Treatment.—On the lines already indicated.

Medication.—Vichy twice or three times a day, as may be necessary. For the pain particularly, the aconite and belladonna mixture as described in Case II. Strychnine sulphate, $\frac{1}{100}$ th of a grain three times a day as a general tonic.

19th.—Feeling much better. Cramps and pains have been but slight. Has no appetite. Continue the aconite and belladonna mixture as before, and, as there is still some tenderness in the epigastrium, to take bismuth subnitrate, 10 grains, twice a day. For the anorexia, nuxvomica in small doses.

23d.—He is feeling very much better. Leaves for home.

Several months later I heard from him. He felt well, had gained greatly in flesh, and was about to get married.

CASE IV.—H. S., November 5, 1899. The first part of the history has already been given.

She gets dizzy spells. Is afraid to trust herself on the street alone. Has headaches; at times her head is so dull that she does not comprehend what is said to her. She has a feeling of fulness in her stomach. After eating she must keep herself in the erect position for a while, as she regurgitates some of her food if she sits or lies down. It takes nearly six hours (her statement) for the food to pass out of her stomach and till she is again comfortable. There are no eructations. Her appetite is fair. When she is hungry she gets a pain in her stomach. Sometimes she gets a pain there during eating, which will last for a while. What she complains of most is a *burning and heat* in her stomach, which sets in shortly after she has finished her meal and continues for a long time. Sometimes this burning is exceedingly distressing. She eats very little, a little milk or oatmeal in the morning, a little soup and a small bit of meat for dinner (noon), and a soft-boiled egg or two, with a little milk and a small slice of bread, for supper. She drinks much Seltzer water (artificial) through the day. Bowels very costive; stools very little and in the form of scybala, and she must press much and hard to discharge them—not more than two or three at a time. Much flatulence. Sleeps very badly; she sleeps with her mouth open, and the drying of her mouth and throat wakes her up at frequent intervals.

Examination.—Teeth good. Tongue coated with a light white fur. Nothing abnormal about the abdominal organs. Stomach apparently normally located. Both nares obstructed.

6th.—Test breakfast, Ewald and Boas, one and a half hour. Removed 100 cubic centimetres of bread and

fluid; ordinary appearance. Settled, on standing, into two layers, bread well worked up. Strong and characteristic reaction to tests for hydrochloric acid. Total acidity, 93. *Rennet* +; *pepsin* +.

Diagnosis.—Hyperacidity, with some degree of atony.

Treatment.—Along the lines laid down. By reason of the constipation, much stress was laid upon the dietary regulations for this, and upon the drinking of a proper amount of water—plain, ordinary hydrant water. Vichy at 11 A. M. (about three hours after breakfast) and at 5 P. M. Massage. Electricity. To have polypi removed.

14th.—She is being treated for her nose, has had several of the polypi removed. She breathes much better. Her dizziness and headaches have almost entirely disappeared, she sleeps much better, and she is feeling much improved in every way. She has had no burning at all in the last four days. The hard-boiled eggs are well digested and she feels good after them. She likes them very much.

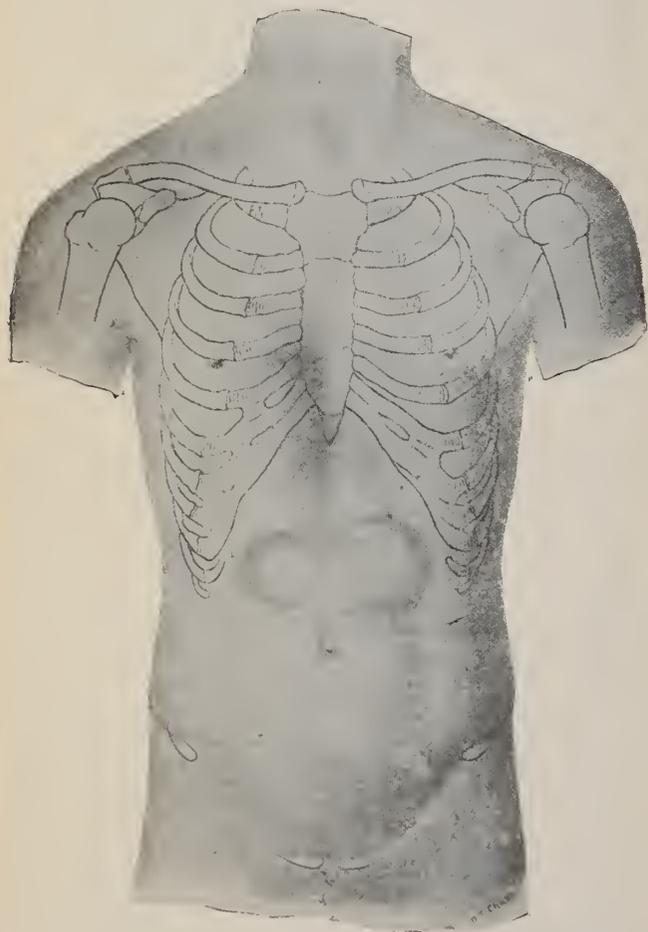

23d.—Continues to do well. Bowels acting satisfactorily. Comes up alone now.

She was under treatment but a short time longer (a few weeks) when an attack of influenza set in, which laid her up for some time. I have not seen her since, but have been told by a friend that she has not since had any trouble with her stomach.

CASE V.—December 25, 1899. J. B., a boy, æt. twelve, Polish-Jewish, four feet three inches tall, very spare in flesh. Has a good-sized head and appears a bright, intelligent lad. He goes to school and is well up in his studies, astonishingly so for a boy not many years in this country. After school he romps about in the street with other boys for a time and then goes in to study. His grandmother, who brought him to the clinic, said that he had a frightful temper, *that he was easily enraged and then would act like one possessed, breaking things and throwing things, whatever he could lay his hands on, at the persons about him. At such times he became actually dangerous to the family.* It was said he would not eat. When questioned, he said he could not eat, because, if he ate like other persons, he suffered great pain and would have to vomit much. Even as it was, he had some pain after eating and vomited some. More definitely stated, the history of his trouble and its character is as follows: He was perfectly well up to a year ago. Quite some time previous to that period *his mother became mentally deranged* (a sort of melancholia, I should judge from what I was told), and after she had been treated here without benefit it was determined to send her to her people in Poland. Her passage was secured and the boy was sent with her as guardian. He brought his mother safely to her destination, to her people in Poland, and remained with her for six months, and then, not being satisfied, determined to return to America. He got to Hamburg without any difficulty, but there was refused passage over on account of sore eyes (a chronic blepharitis marginalis is still in evidence). He cried bitterly and would not be comforted. Finally some kind-hearted sailors of the ship's crew took pity on him and smuggled him into the steerage, where he remained and sailed with the vessel. His bowels had always been regular and he had been able to eat anything and everything, but on the boat he became constipated. He asked the ship's surgeon for some medicine, but for some reason or other could not get any. His bowels remained constipated, pain set in in his stomach, and he began to vomit. Gradually, after three or four days, his

bowels moved somewhat and he felt relieved a little, but shortly thereafter, and particularly after landing, he again became constipated, obstinately so, the pain in the stomach became more marked, and the vomiting grew more frequent. The pain was particularly severe after eating ordinary food, and so he gradually reduced his diet until it consisted almost entirely of bread and coffee or bread and tea.

The pain is felt in the epigastrium; it is both a pain and a sense of pressure. After vomiting he feels relieved. Usually the quantity vomited now is not more than one or two tablespoonfuls; occasionally, and particularly if he should eat something out of the usual, he may vomit all that he has taken. He said that, if he wished to, he could control the vomiting, that is, he

CASE V.—When the stomach was filled with air, the Traube triangle was rounded out and the epigastrium presented this appearance.

could hold in, but then he would have to suffer the pain. He, therefore, preferred to press out a small quantity of what he had taken in and get relief at once.

Examination.—Teeth good. Tongue clean. From the ensiform cartilage to the umbilicus, 14 centimetres. Nothing abnormal on inspection or palpation except tenderness to pressure in the epigastrium, more marked in the left than in the right half. Stomach normally located, normal. Other organs normal.

26th.—Came with a test breakfast, Ewald and Boas. By reason of the distance he had to come, it was nearly an hour and a half before the tube was introduced; nothing but a little frothy mucus was obtained. *Second test breakfast:* after three quarters of an hour the tube was introduced and 50 cubic centimetres of stomach con-

tents were removed. The bread appeared as in flocculi, not well worked up. The fluid was of the ordinary appearance. Reaction to blue litmus +; reaction to Congo + (strong); reaction to resorcin (Boas) + (strong); total acidity, 57.

The diagnosis was not very clear. The large flocculi of the bread I attributed to hasty eating, and he acknowledged that he always ate very fast, so that he might get away quickly to school or to play out in the street. The obstipation I looked upon as due to the lack of proper food. I advised his grandmother to give him but little fluids (so as to avoid any undue distention of the stomach) and more solids; particularly, for his lunch and dinner, to have broiled meat and some little vegetables or stewed fruit.

31st.—He could not adapt himself to the solid food, and, as he did not get the other, he starved somewhat. Prescribed a diet of oatmeal, milk, and meat broths. Prescribed a powder of bismuth subnitrate, cerium oxalate, and rhubarb, to be taken four times daily (for the pain in the stomach and the constipation).

January 3d.—He reported himself as doing well. He has not vomited since he was here, and for the last two days he has eaten meat, raw apples, etc. The epigastrium seems somewhat protuberant, and he complains of some pain there, from 4 to 6½ centimetres from the ensiform cartilage (downward).

7th.—Inflated his stomach. When it was filled with air, the Traube triangle was rounded out; the epigastrium presented the appearance shown in the accompanying illustration.

To the left of the median line there was loud resonance down to within one half centimetre of the umbilicus. On the right of the median line there was some prominence, as shown, with resonance of nearly the same tone as on the left.

14th.—Does not vomit now, though occasionally a very little of the food is regurgitated. His bowels are still costive, and he must strain very much, and sometimes this makes him vomit. He says that since the inflation he has had less pain in his stomach.

21st.—His aunt, who came with him to-day, said he still ate very fast and inordinately much. When he regurgitates, it is mainly water, sometimes there is a little bread with it; very rarely does any meat come up. Massage (abdominal).

28th.—Vomited three times last week—Wednesday evening, some tea; Thursday, very little; Saturday, most of his dinner. The bowels have been costive and irregular, the movements being either very hard or loose and watery (after a laxative).

February 11th.—Test breakfast taken in my office. One hour afterward, 60 cubic centimetres removed; usual appearance. Rapid reaction to tests for hydrochloric acid. Total acidity, 81. Free hydrochloric acid (after Mintz), 33.

The diagnosis was now clear. It was a case of hyperacidity. (The reason for the difference in the results of the two examinations is apparent and need not be dilated upon.)

March 1st.—When his bowels move, then his symptoms subside; as soon as they become costive again, all his complaints are renewed. He has noticed that warm tea, particularly, taken after lunch or dinner, will cause him to vomit. He complains of a *burning* and a *sourness* in his stomach. To take Viehy (French), half a glass, three times a day; glycerin, one third of a teaspoonful,

three times a day. There is much trouble about his diet. He has not had it as it was directed, even from the beginning—whether from poverty or from carelessness, I do not know. Thus, he has no egg for breakfast, nothing but bread and weak coffee. He thinks, perhaps, they cannot afford eggs now. To tell his grandmother his diet must be attended to.

May 13th.—The same old story. The same complaints on his part, and the same complaint as to his awful temper and carrying on by his aunt. He had himself weighed at the drug store; weighs 70 pounds—a gain of 5 pounds over last summer's weight. Massage.

27th.—Bowels moving satisfactorily. Test breakfast as before. Total acidity, 76; free hydrochloric acid, 23. Massage.

June 10th.—Bowels moving fairly. Now weighs 72 pounds. Still complains of some pain in his stomach. Bryonia.

17th.—Bowels continue regular. Complains of acidity. Had to reprove him about dietary matters and as to drinking water. To take Vichy.

July 22d.—Bowels not so regular; move every other day only, and the fæces are like pap. Vomits but very rarely. Weight now, 76 pounds.

August 5th.—He says he has not felt so well for a long time. Bowels act regularly.

26th.—Same as at last report. Weight, 78 pounds.

September 16th.—Bowels again somewhat costive for the last few days; they move every other day, but only very little. Has vomited some since. He thinks they will *right themselves* shortly. Massage.

December 9th.—He came in to see me to-day, as I had sent for him, being desirous of knowing how he had got along. He feels well. Has no pain in his stomach any more. His bowels act regularly every day. He does not vomit except after a fit of anger, and then only very little. He can control himself much better now and does not quarrel so much with his grandmother. He weighs now 80 pounds. Looks taller. He has stopped school and is going to work.

There is only this to be added: From the period noted in the history, massage was given with greater frequency than previously, and, with the constant admonitions as to diet, was very effective in bringing about a soluble state of the bowels. A malt preparation prescribed was, I think, of some service, both in promoting a better digestion of the carbohydrates (thereby restricting the amount of flatus developed) and in influencing the intestinal peristalsis.

There can be no question, I believe, that the constipation was here the direct cause of the hyperacidity, though undoubtedly the neurotic substratum in the boy was in a measure responsible both for this and for the obstinacy of the constipation.

CASE VI.—November 14, 1900, Z. L., æt. twenty-six; single; Russian; a portrait artist (crayon and pastel); five feet four inches in height; weight (without overcoat), 115 pounds. Smokes; formerly ten cigarettes a day, now four cigarettes and two cigars a day. No drinker. Up to four years ago, he was perfectly well. Since that time he has had trouble with his stomach, and it is growing worse and worse. He complains of pain in his stomach, of great burning therein. He has no

appetite; he cannot eat, and when he does eat it does not agree with him; it lies heavy in his stomach and the burning comes on. He is growing thinner day by day. Bowels very constipated for the last four years; must always take something to move them.

Examination.—Teeth fairly good. Tongue coated in the posterior two thirds with a light white coat. From the ensiform cartilage to the umbilicus, 15 centimetres. No tenderness in the epigastrium.

Stomach.—Left thoracic region, gastric resonance, and over the left epigastrium down to the crease. Left epigastrium from 6 centimetres below the ensiform cartilage down to 21 centimetres, resonance, then dulness. Right epigastrium dull to the crease, then resonance, which continues to 20 centimetres. Some splashing noticed to the left and near the line of the umbilicus. Water, 8 ounces. With the knees drawn up and the mouth open, no splashing in the epigastrium. Liver and spleen normal.

Test breakfast; 357 cubic centimetres of fluid and half a water roll. An hour afterward I removed 260 cubic centimetres of bread and fluid (mainly fluid—four fifths fluid, one fifth bread). Reaction to tests for hydrochloric acid, strong and characteristic. Total acidity, 61. Free hydrochloric acid (after Mintz), 35. Sp. gr., 1.015.

Diagnosis.—Hyperacidity.

Treatment.—Mainly dietetic. For the constipation, certain modifications of diet. Water. Massage.

29th.—Doing nicely. Bowels acting regularly. He eats very much, as he expressed it, almost wolfishly, and then feels heavy. Told him to make four meals rather than three, and not eat so much at one time.

January 20, 1901.—He is doing very well. He has gained 5 pounds in weight. His bowels have been acting regularly. He has worked steadily from 9 to 4 from early in December, something he has not been able to do before since the beginning of his illness.

March 11th.—Weighs 127 pounds now. Bowels regular, move daily and freely. Came with a test breakfast to-day. Total acidity, 51. Free hydrochloric acid, 17.

CONGENITAL MALFORMATIONS OF THE UPPER EXTREMITY.

By CARL BECK, M. D.,

NEW YORK.

THE great scientific and practical value of the Röntgen rays is evident in the study of congenital malformations of the bones. Skiagraphy of the extremities especially has given more valuable information than dissection. The exact anatomical diagnosis which it enables

us to make informs us whether surgical interference is possible, and, if so, outlines clearly our *modus operandi* beforehand. The ingenious operations of Bardenheuer (division of the ulna for carpal implantation), and von Eiselsberg (transplantation of a toe), and the work of Kirmisson, Vulpius, Middleton, Pagenstecher, von Bardeleben, Joachimsthal, Schede, Lambert, and Grunmach furnish most brilliant testimony to our progress in this direction.

Fortunately, the most frequent abnormality is the one which can easiest be remedied, namely, *polydactylism*. If there is but a rudimentary finger attached loosely by a pedicle and not containing any phalanges at all, removal is very simple.

Case I (skiagraph Fig. 1) illustrates this type. The patient is a boy four months of age. The family history

FIG. 1.—Polydactylism, showing rudimentary fingers loosely attached by a pedicle and not containing any phalanges.

is good. The parents came here from Roumania seven years ago. The child is the first born. Removal was naturally easy. It is of interest to note the partial fusion of the third and fourth metacarpal bones, a condition which would hardly have been diagnosticated without the Röntgen rays.

But when, as it is the rule, there is a true supernumerary digit articulating with another phalanx or the head or side of a metacarpal bone, the site of exarticulation must be well known before the operation. Otherwise the better-developed phalanx may be sacrificed.

Case II, illustrated by Fig. 2, represents this type in a new-born girl. In this instance the family history is good. The parents are healthy, and came here from Russia five years ago. The child is the first born. Both hands show supernumerary digits, each one containing three well-developed phalanges. Exarticulation was

FIG. 2.—Supernumerary digits, each one containing three well-developed phalanges.

done three weeks after her birth, under the guidance of the Röntgen rays.

Case III, illustrated by skiagraph No. 3, represents the same type in a much more important light, since the supernumerary digit is attached to the thumb and articulates with the first metacarpal bone. The patient, a boy of six weeks, is the second child. The family history reveals nothing of interest. The parents are in good health, and came here from Austria two years ago. The supernumerary digit was separated from the first phalanx of its fellow and exarticulated.

Syndactylism, while not so frequent as polydactylism, also represents a large group of cases of malformation of the upper extremity, and is likewise well amenable to operative interference.

FIG. 3.—Supernumerary digit, articulating with the first metacarpus.

FIG. 4.—Syndactylism.

Case IV (Fig. 4) illustrates the complicated type of syndactylism in a boy four months of age. The family history also shows nothing abnormal. The child is the first born; the parents are in good health and came here from Hungary eight years ago. The second, third, and fourth digits appear to be fused together, each one of them, however, possessing its own nail. The skiagraph, Fig. 4, shows fusion of the first and second phalanges of the third and fourth digits, while their third phalanges are free. The little finger is more developed than the slightly deformed thumb. The carpus is not ossified yet, and shows no shade therefore. Under the guidance of the Röntgen rays it was easy to divide the phalanges. The middle finger was protected by a large longitudinal flap taken from the dorsum manus. The two other fingers were covered by their own integument, longitudinal flaps being formed from the palmar surface for the second finger and another one from the dorsal aspect of the fourth. The final result is good.

FIG. 5.—Skiagraph of Fig. 4, showing fusion of the first and second phalanges of the third and fourth digits and deformed thumb.

Case V, illustrated by skiagraph No. 6, shows congenital exostosis in the second phalanx of the index finger of a boy who was born in Germany nine years ago. The family history shows nothing abnormal. The Röntgen rays demonstrated the character of the osseous growth clearly. In view of the presence of functional disturbance, removal with the chisel was undertaken.

Congenital *deficiencies* are naturally much less amenable to correction. But that even in desperate cases of this kind surgery is not without resources is made evident by the transplantation of a toe to the hand, successfully undertaken by von Eiselsberg.

FIG. 6.—Congenital exostosis in the second phalanx of the index finger.

In a case of *brachydactylism* combined with *ectrodactylism* the Röntgen rays are also of great value. In Case VI, for instance, that of a boy of three months, there were five rudimentary fingers (Fig. 7). The skiagraph (Fig. 8) shows the presence of one phalanx of the thumb and of two phalanges of each of the other fingers. The child was the first born of German parents, who came here five years ago; the mother is healthy; the father was suffering from tuberculous knee at the time of the birth of the child, and died from general tuberculosis a year afterward.

Under the guidance of the Röntgen rays I performed a flap operation, on the principles set forth in Case III, between the first and second finger-rudiment. Thus a

FIG. 7.—Brachydactylism and congenital constriction.

fairly good thumb was created. The case, however, offers two more points of interest. In the first place, there was congenital fracture of the ulna and radius at

FIG. 8.—Skiagraph of Fig. 7, showing the presence of one phalanx of the thumb and of two phalanges of each of the other fingers and fracture of radius and ulna.

FIG. 9.—Consolidation of fractured ulna and radius (Case Fig. 8) after extraction of the wire and union of the muscular separation at the upper portion of the arm.

their lower third, as illustrated by skiagraph Fig. 8. The forearm could also be bent easily at the seat of the fracture. After wiring the fragments, as illustrated by Fig. 9, union became perfect.

FIG. 10.—Total congenital constriction of upper portion of humerus.

There was, furthermore, congenital constriction (Fig. 10) at the region of the surgical neck of the humerus, where a deep furrow encircled the whole circumference of the arm. Palpation was unable to detect any soft tissues between integument and bone. An exploratory incision revealed the presence of the fragments of the biceps, triceps, and deltoid muscles. Their edges were refreshed and united with catgut. For relaxation, two deep wire sutures were introduced from without.

FIG. 11.—Congenital club hand, associated with absence of radius and ulna.

The result is fair, according to the last report, fourteen months after the operation.

It may be added that the otherwise well-developed right hand shows a moderately deep constricting furrow

near the metacarpophalangeal junction of the middle finger, which did not seem to demand surgical interference.

FIG. 12.—Skiagraph of Fig. 11, showing absence of radius and ulna and of two metacarpi and digits.

Case VII (Fig. 11) is a case of congenital *club-hand*, associated with absence of the radius and ulna. That there are only three fingers is shown by the photograph, and that but three metacarpal bones are present becomes evident by the skiagraph No. 12. The patient is a boy, six weeks of age, born in New York. The family history is good. The parents came here from Italy two years ago. The father is sixty-six and the mother forty-one

FIG. 13.—Formation of thumb from the first metacarpus. (Compare Figs. 11 and 12.)

years old. Both are in good health. There are three previous children, all of whom are well.

The left arm of the boy is normal, with the exception of the thumb, which is partially ectrodactylic, like the

thumb reproduced in skiagraph Fig. 1. I attempted to improve this deplorable condition by creating a thumb after the principles carried out in Case VI. For this purpose a dorsal incision was made first, down to the first metacarpal bone, which I divided longitudinally, thus making a kind of bifurcation. The phalangeal end was severed entirely, but the carpal end, after being fractured longitudinally, was left in slight connection with the metacarpal bone. Thus a new bone was obtained, which was surrounded by dorsal as well as palmar flaps. There was little trouble during the after-treatment. How far this new fourth finger can be utilized cannot, of course, yet be known, the child still being under treatment. The skiagraph Fig. 13 shows its position.

The treatment of the club-hand will be attempted later on. Reginald H. Sayre (A Contribution to the Study of Club-hand, *Transactions of the American Orthopaedic Association*, 1893, page 208) has obtained very good results in correcting club-hand by resection.

Case VIII, which was observed before the discovery of the Röntgen rays, may be added in view of its rarity. It represents congenital absence of the arms and forearms (Fig. 14), the head being fairly well developed. The patient, a boy, born in New York, was ten months old

FIG. 14.—Congenital absence of arms and forearms.

when the photograph was taken. The parents came here from Germany fifteen years before the birth of the child. Both are fairly well, but poorly nourished. One sister died from meningeal tuberculous. Two brothers and one sister are alive and healthy. The patient died from dysentery when one year old.

It may be noticed that not one of these eight deformed children was born of American parents.

The operative procedures recommended must, of course, be done under the most rigid aseptic precautions.

THE MENTAL DISEASES OF CHILDHOOD.

BY WILLIAM B. NOYES, M. D.,

NEW YORK,

ATTENDING NEUROLOGIST TO THE DEMILT DISPENSARY.

DIFFERENT authors have made various attempts to classify in a satisfactory manner the different epochs and periods of a child's life from birth to adolescence. Christopher, in an article in the *Child Study Monthly*, 1897, calls attention to three critical periods in a child's life: First, infancy (the first three years), with the gastro-intestinal tract as the place of least resistance; second, the fatigue period (seven to nine years), when fatigue occurs most readily, when the heart is most liable to be injured, when "general laziness" and certain other characteristic symptoms occur; third, the period of puberty (twelve to fourteen years).

So far as concerns the maldevelopment or diseases of the brain and nervous system, the first period is chiefly associated with the appearance of idiocy and the more gross nervous symptoms, principally of a motor nature, such as convulsions, muscular twitching, or possibly paralysis. In the majority of cases these nervous symptoms are due directly to trouble in the gastro-intestinal tract or to allied conditions of faulty nutrition, such as rhaehitis.

So great are the dangers of any mistakes in the feeding of infants that even the most ignorant parents make some efforts to follow the advances of medical knowledge in dietetics, and pay close attention to the food given during the first years of infancy. But when the child begins to attend school, the close attention paid to diet and hygiene is relaxed, and the first real strain on the child's nervous system begins. These two reasons make this "fatigue period" of from seven to nine years no artificial distinction, but a genuine factor in the evolution of the neurotic child.

The nutrition of a child is not an unvarying or constant factor. Digestion itself varies with the condition of the stomach, the food, and the exercise of the child, and these in their turn are modified in their effect by the weather, the season, and domestic economy. Growth may be expressed in height or weight or, in the terms of histology, may chiefly exert itself on the development of muscle, bone, or fat or in the more indefinite physical and mental activities.

A careful study of the "fatigue period" emphasizes the fact that the growth of the child, both mental and bodily, is more or less rhythmical in its nature. Some authors have devoted much attention to this periodical, or rhythmical, element in ways that often seem rather fanciful, and yet the underlying fact is undeniable. The development of the whole body, as well as of each individual organ, takes place with continual alternation of activity and rest. Every extensive intellectual advance corresponds with a retrogression in bodily relations. Strong advance in one intellectual activity carries with it

corresponding depression of other internal activities. External and internal causes hasten or retard the periodical recurrence of action and reaction. Siegert, in a study of this subject, has pointed out that such periods occur in the first year of school life, again in the third and fourth years, and later in the sixth or seventh year of school.

As a result of such a period of retrogression, the following symptoms may occur: Fatigue, dulness, carelessness of all sorts in work, slovenliness, and a general reversal of the ordinary characteristics of the child.

In the earlier period of infancy the usual disturbances of the nervous system are largely motor. In an infant of neuropathic organization the convulsive movements or general eclampsia may readily occur, the tendency to which may persist to later life as epilepsy. The onset of the acute infectious diseases of childhood is marked in many cases by a convulsion. Not only this convulsion, but the fever that follows it, is dependent to a large extent on the impressible nervous system. In many children an elevation of a few degrees of temperature is always followed by a delirium, often quite out of proportion to the height and duration of the fever. This may be called the earliest tendency to acute mental disturbance to be seen in childhood, indicating the same degree of instability of the higher brain centres that the convulsion shows of the lower brain or spinal centres. It is usually considered a definite stigma of a degenerate heredity to react in this way.

In the "fatigue period" (seven to nine years), in place of the tendency to convulsions, a different set of motor symptoms appear, such as twitching of single muscles or groups of muscles, of which the choreiform movements are the most familiar type. Chorea and the tics and certain other rarer conditions showing similar movements, but more purely reflex in their nature, occur at this time. Some, like tetany, are caused by infection; others are more distinctly hereditary. The minor degrees of choreiform movements are not so very different from the movements of simple restlessness of a child, which school teachers note are always increased near the close of school hours on cloudy days, in the spring, and when the child has been without exercise. All through infancy and during the earlier years of childhood, purely sensory symptoms are rather rare, with the exception of occasional headaches or pains of a more or less reflex nature.

The uncertainty of the sensory symptoms of a young child are familiar to any one who has tried to trace to their source the reflex sensory disturbances that occur so frequently in children. Nocturnal enuresis, the symptoms due to intestinal parasites, adenoids, enlarged tonsils, eye-strain, and the earlier forms of masturbation are often sensory in their nature, though the reflexes caused by them are chiefly motor. Perhaps the earliest sign of temporary or permanent sensory weakness in the nervous

system of a child is failure to sleep properly, sleep in a baby standing next only to nutrition in its effect on the health and development of the child. After early infancy has passed, the study of sleep becomes even more interesting.

While most of the mental faculties characteristic of adult man are present before the third year, it is the exaggeration of some mental faculties and the slight development of others that distinguish a child psychologically from an adult. Imagination during early childhood will be at its highest point. Not only such individual mental characteristics as fear, love, selfishness, vanity, generosity, jealousy, grief, or anger may be strongly developed, but the most rapid variations from one to the other may occur and are certainly not pathological. In its play, a child's imagination stops little short of hallucination. These mental traits may be brought under control to some extent as the months pass by, but it is curious to note how the earlier traits reappear during sleep, especially in nightmare and mild delirium. A child who is fearless by day may become frantic with fear by night. Free as the imagination may be by day, at night it often seems to run wild with all sorts of queer ideas and fancies. Given the toxæmia of a poorly digested meal or a little fever, and this superexcitability of the brain and special senses becomes very marked. In a child with a definite neurotic heredity, nocturnal delirium is caused by the slightest febrile disturbance, just as convulsions easily occur in younger children of the same sort under the same conditions.

Pavor nocturnus, or night terrors, though not associated with an elevated temperature, in many cases may be said to be the relic of some previous febrile delirium as a sort of brain habit! just as the convulsion recurs from habit in some children after a first attack. Pavor nocturnus may be considered, like the temporary delirium of a degenerate child and the mental disturbances from intoxication already referred to, as the type of transitory psychosis to be met with during early childhood.

The causes of night terrors are numerous. Their close relation to abnormal conditions of the nasopharynx are emphasized by authorities on the nose and throat, who lay stress on adenoids and enlarged tonsils as ætiological factors in most of these cases. But these abnormalities of the lymphatic tissues are usually closely dependent on the narrowed, deformed palate so common in the degenerate child. The relation to epilepsy and mental weakness is evident in many cases. Some authorities believe that pavor nocturnus is really a transitory hallucination of sight due to increased irritation of the brain cortex. It may be a loss of the higher functions and an exaltation of the lower cerebral functions. Soltman believes the visual hallucinations indicate over-activity of the central sensory areas, such as the pulvinar of the optic thalamus, the corpora geniculata and quadrigemina, or the cortex of the occipital lobe and optic tract.

The following case of pavor nocturnus indicates the variety of ætiological factors that may exist:

CASE I.—Michael McN., aged twelve years, treated at the Demilt Dispensary in 1897 and occasionally since. His father was alcoholic. He had a convulsion when eleven months old. He has had a slight left hemiplegia since the convulsion, only perceptible at the present time from slight spasticity and weakness of the arm. From eight to twelve years of age he suffered from night terrors, occurring two or three times a week. He wakes up with a scream and seems to have had a dream or a vision. He gets up and walks around in a somnambulistic condition, from which it is difficult to rouse him. He has occasionally attacks of morbid fear by day. Without any noticeable exciting cause, this condition develops, lasts a few minutes, and then disappears. In physical condition he is anæmic, thin-chested, the physical examination being negative. Examination of the eyes shows hypermetropia and astigmatism. Appetite poor. In this case there is a strong hint of an epileptic history in which, as a result of the old condition of hemiplegia, occasional mental attacks of an epileptic nature are substituted for the ordinary motor convulsion. The most common causes of pavor nocturnus were absent in this case. Treatment by iron and a little bromide would promptly stop the symptoms, which occasionally returned whenever the boy became overworked. In the subsequent history attacks of fear by day are noted. He has also had chorea twice. He is practically well at present.

The most common result of over-strain during the fatigue period will be a breakdown in the general health. An average child at this age will show his diminished power of resistance as a rule by succumbing more readily to the infectious diseases. If the motor or sensory neurone is the weakest place, a nervous disease may appear.

The period from seven to eleven has been characterized as the period of coordination of motion and emotion. Chorea, epilepsy, asthma, somnambulism, migraine, myopia, and converging strabismus may be mentioned as neuroses of this period. The period of puberty is the third critical period of a child's life and is of pre-eminent importance in a study of the development of his nervous diseases. Viewed as a study of personality alone, it is one of the most instructive studies for a psychologist to consider. The mental growth of a child makes no sudden jumps from the time of birth to puberty, though the first eighteen months rapidly develop the majority of the mental faculties to a point at which they can at least be recognized. Without attempting to define consciousness and personality, the fact of personality becomes evident enough in the case of an individual child at an early period. It is not expected that any sudden change will occur in the personality of this child. If it could occur, the condition would be something of the nature of insanity, of which early childhood gives only rarely an example.

In conditions of perfect health the personality is something continuous, uniform to the extent of maintaining an equilibrium. That the ego must change and

is always changing, we all realize. Personal identity depends on the states that are fixed being greater and more powerful than the states added to or detached from the stable group. Normal variations are familiar to the self-consciousness of every one. A normal individual may frequently in a single day change from cheerfulness to despondency, and change in a decided way. Such changes are much more frequent in a child. The explanation is that, even in these cases of ordinary variation, the variable parts of the personality have exceeded the normal ratio to the unchangeable parts. The stable elements have been impaired temporarily, but have not disappeared. While it is natural and normal for a child to be happy, as a matter of fact, the opportunities for unhappiness are often greater than in adult life. While real sorrows have not yet been experienced and the struggle for existence has not yet begun, this variation of temperament and of personality itself is more rapid and frequently repeated than in an adult. The stable part of the mind has not yet been fixed; the variable is the chief factor and is controlled only by the discipline of home and school and whatever inherited power of self-control may exist. During the fatigue period these variations of the personality are often marked, but do not, as a rule, persist for any length of time. But when for any reason this temporary change of personality becomes fixed and persists, a new mental and physical condition has developed. Such a sudden and permanent change is physiological at one period of life only, and that is during the period of puberty. At an earlier and a later period a rapid change of personality which persists is pathological, and may rightly be termed a psychosis or mental derangement. The mental changes of the period of puberty are not less marked than the physical. The period of early infancy, when the personality of the young infant is related to nutrition with its original comfort and discomfort, desires, and aversions, has passed. The slow, almost imperceptible growth of all that pertains to personality has been going on from year to year. At puberty a new group of sensations, emotions, and ideas is developing. This afflux of unaccustomed psychological states tends to modify profoundly the constitution of the ego. It feels undecided. The minor variations of the earlier years become more frequent and pronounced. Latent discontent is felt, and discomfort, the cause of which is unknown. Gradually the new elements are assimilated by the old ego, and enter into it, but at the same time make it different. The ego has changed, a partial alteration of the personality has been accomplished, the result of which has been to constitute a new type of character, the sexual character. The most common traits of this period may be summed up as follows: 1. Frequent and causeless change of moods. 2. Expression of "Weltschmerz," or universal mental depression, during the jolliest hours. 3. Sudden changes of the habitual line of thought or incoherence of normal

thought. 4. Talkativeness, echolalia, mimicry, and extravagance. 5. Impulsiveness in action. 6. A sense of exaltation and ambitious delusions of greatness alternating with feelings of depressive unworthiness. In a child with poor heredity and unhygienic surroundings the period of puberty is almost certain to develop some organic or functional disorder. Among the organic troubles associated with this period may be mentioned chlorosis, menstrual defects, certain skin diseases, such as acne, hay fever, acute rheumatism, tuberculous disease, and arrested or excessive growth; of nervous diseases, epilepsy, chorea, and hysteria; of moral or temperamental changes, incompatibility of temper, perversion of the moral sense, unfounded aversion to relatives or friends; of mental diseases, certain psychoses which we will study in detail later.

A close analogy exists between the normal mental characteristics of the period of puberty and the symptoms of hysteria. Hysteria not only occurs fairly frequently in childhood, but it is one of the expressions of the fatigue period and later of the period of puberty and adolescence. While the motor and sensory symptoms of hysteria are so common as to be pathognomonic, the mental symptoms are perhaps even more constant in their presence. Loss of will power, or perverted will power, is more frequently an evidence than the classical sensory stigmata of hysteria so much emphasized in adults. Loss of normal inhibition underlies mental and bodily symptoms alike. Apart from the more familiar motor, sensory, and mental symptoms of hysteria, the following symptoms of a mental nature are sometimes seen and were described first by Hensch: 1. Complete or partial loss of consciousness, sometimes as a fainting fit, sometimes akin to somnambulism. 2. Attacks of drowsiness of long duration. 3. Delirium, including *pavor nocturnus*. 4. Hallucinations and morbid ideas of various sorts, especially of a religious nature. 5. Catalepsy, consciousness being suddenly lost or weakened, the child standing with a fixed or staring look or gradually sinking down. This is a condition closely allied to *petit mal* or the dream state. 6. Mental symptoms alternating with such motor symptoms as hysterical convulsions or stamping on the ground or other movements expressing passion; hysteria major, or hysterio-epilepsy. 7. Mental and sensory symptoms combined. Severe headache and pains in various parts of the body, or zones of hyperæsthesia.

Innumerable as the variations of hysteria in childhood seem to be, these mental symptoms, admitting the rarity of some of them, are of decided importance because they represent certain mental conditions which parents and medical advisers might easily mistake for genuine insanity. It is to emphasize the comparatively innocent nature of many of these psychoses of childhood that the condition needs emphasis. The following cases illustrate this:

CASE II.—H. R., aged twelve years, was attending, at the time I saw him, a small private school and later a large boarding school for boys. When thirteen years old he became subject to mental depression and had frequent crying spells. He said that the other boys hated him. He accused himself and others of what might be interpreted as masturbation. He was unwilling to mingle with the other boys, and misinterpreted their casual remarks as cruel or insulting. He had at times choreiform movements, but never genuine chorea. His letters home were filled with the most heart-rending statements of his misery, but his family found that he was greatly exaggerating the relations between himself and the other boys. This general condition lasted two years and finally disappeared. The family history was as follows: His father was a brilliant man of business, of poor health (probably tuberculous), and had been subject to attacks of mental despondency at about the same age that his son had it. In both father and son the mental condition never returned. In every other respect the family history was negative. The boy had no symptoms or stigmata of degeneration, except a certain amount of eccentricity.

This case is to be classified as a definite psychosis of puberty. It certainly was characterized by a temporary change of personality of the type already described. Hysteria could only be a sufficient diagnosis in the sense of the mental variety of hysteria. But it is well to note that most of his symptoms were merely an exaggeration of the physiological symptoms of puberty. The prognosis was fairly good instead of gloomy.

The next case is somewhat similar.

CASE III.—Sidney G., aged thirteen years, treated in the Demilt Dispensary in 1898. Heredity negative. Typhoid fever and diphtheria several years before. In April, 1897, he was treated for restlessness, attacks of crying, anæmia, and insomnia. He had masturbated and would talk in an obscene way before his mother. He complained that the other boys abused him. Later, he complained of headache, pains and ringing in his ears, and mental depression. He cried frequently, because he believed "everybody was making fun of him." He was hyperæsthetic and had a sensation of globus and "ovarie." He had grown taller and was more reserved in his manner than at first and would not own up to former bad habits. He had slight choreiform movements. He recovered completely after six months.

This case belongs to the same class of cases of mental changes of the period of puberty. It is more distinctly of the nature of hysteria than the previous one.

In sharp contrast to these cases of a more or less hysterical nature, characteristic of the period of puberty, and representing simply an exaggeration of the physiological symptoms of the period, the following case is of interest as representing a type of genuine insanity:

CASE IV.—Walter B., aged fifteen years, treated at the Demilt Dispensary in 1897. His father has melancholia and at the time of this history was confined in an asylum. His brother was under treatment for some form of mental trouble. Walter had attended school until the previous month, when he began to act queerly. He had been growing rapidly and gave a history of mas-

turbation. When first seen, he was suffering from a partial loss of memory and was violent at times. He had a little fever and chilly sensations occasionally. When seen at his house, a few days later, he had become violent and tried to "knife" some one of the family. He was sent to an insane asylum, where he recovered in a week. He suffered later from headache, vertigo, and poor eyesight. Physical examination showed a high-arched palate, adenoids, thick ears, large hands and feet, and a narrow forehead.

This case is a typical example of an acute mental trouble in a boy who was of a distinctly degenerate type, with a definite family history of insanity and marked stigmata. His mental derangement was closely connected with the coming of puberty. There was possibly a malarial element, which may have been an exciting cause. Note how easily his will power was overcome by an insane homicidal impulse. Definite fixed ideas were not found.

In this case the dangerous heredity is the important aetiological factor. It will certainly render him liable to insanity whenever he is exposed to the ordinary strain of minor sickness, overwork, or mental worry. Such cases of insanity may be produced at the period of puberty if the heredity is bad and if to the heredity is added anæmia, mental or bodily strain, acute infection, or sexual excess. Nearly all known psychoses may occur during this period, the dementia hebephrenica of Kahlbaum being the only form occurring exclusively at puberty and adolescence. This is a form characterized by a change of superficial emotional conditions, beginning with mental depression, followed by odd, fantastic delusions, eccentric, silly behavior, and intense motor activity, and resulting often in a rapid or gradual passage into chronic dementia or into the condition of catatonia. Frequently the ordinary types of insanity that may occur at this time are strongly tinged or modified with a coloring of hebephrenia.

Of genuine acute psychoses occurring at the period of puberty the following may be mentioned:

1. Melancholia, either simple, passive, or active, with excitement or stupor.
2. Mania, which may be simple, irritable, or of the nature of catatonia.
3. Mental confusion.
4. Hallucinatory madness, hallucinations being possible even in a young child, because sensory impressions become early fixed.

The following progressive psychoses occur:

1. Dementia of puberty (dementia hebephrenica).
2. Simple precocious dementia.
3. Very rarely, general paresis.

Of psychoses resulting from mental degeneration, there are:

1. Paranoia, which is very rare because delusions

cannot appear in a child until systematized concepts or logical thought begins.

2. Periodic insanity, intermittent or circular, which is more common.
3. Phobias, obsessions, and *folie du doute*, which are not uncommon.
4. Kleptomania and dipsomania.
5. Sexual aberration.
6. Impulsive insanity; imperative conceptions, suicidal or homicidal.
7. Moral insanity.

There are also the following combined psychoses or neuropsychoses:

1. Neurasthenia, more especially cerebral neurasthenia.
2. Hypochondria, most commonly of a sexual nature.
3. Hysterical insanity.
4. Choreiform insanity (the mental equivalent of chorea).
5. Epilepsy appearing as a chronic psychosis or a spasmodic dementia, or an acute psychosis as the psychical equivalent of epilepsy.

Lastly, there may be psychoses by intoxication, either of the nature of (1) auto-intoxication, (2) intoxication following infectious disease, (3) alcoholic intoxication.

In closing, it will be well to emphasize that insanity is rare before adolescence, but that the less pronounced psychical disturbances that occur in young children are often the first manifestation of a train of symptoms that are to end only at the development, some years later, of one of the definite clinical forms of adult insanity. There is no sharp dividing line between the symptoms of a neuropathic child and a psychopathic adult.

Symptoms and diseases of a mental nature are better understood by one who has made himself thoroughly acquainted with the special physiology and psychology of a child or adult than by one who limits his knowledge to the elaborate classification of the clinical forms of insanity met with in the text-books.

28 WEST SIXTY-FIRST STREET.

Therapeutical Notes.

For Toothache.—Under the name of Swedish toothache drops, the *Ohio Dental Journal* for June quotes the following from the *Oesterreichische Zeitschrift für Pharmacie* of unnamed date:

R	Clove oil,	}	of each.	10 parts;	
	Cajeput oil,				
	Chloroform,	}	of each.	5 "	
	Acetic ether,				
	Menthol.			3 "	
	Camphor.			1 part.	
				Dissolve. For application to the tooth.

NEW YORK, SATURDAY, JUNE 29, 1901.

THE OLIVER WENDELL HOLMES OF THE MIDDLE AGES.

AT first sight it may seem far-fetched to liken Rabelais to the Autocrat of the Breakfast Table, but the feeling of incongruity will subside, we think, on a little reflection. Rabelais, though originally trained for a monastic life, and though he finally resumed ecclesiastical work and died a curate, was much attracted to medicine early in his career. After his suspension from a monastic order he studied medicine regularly, was admitted into the profession, and became a lecturer in the faculty of Montpellier. That he took up medicine not in a spirit of dilettanteism, but as a subject to which he genuinely bent his energies, is abundantly evident from Dr. Flint's account, published in this issue of the *Journal*, of his remarkable conceptions concerning certain physiological problems; and it is further evident from his zeal in mitigating the physical ills of his flock after his resumption of clerical duties.

Holmes, too, did not forsake medicine. Though he was a practitioner for but a very short time, he made several notable contributions to the advance of medical knowledge, and he continued as a professor in the Harvard Medical School until he was an old man. Truly, when once the study of medicine has thrown its charm around a man of parts, he never deserts it. Neither Rabelais, the greatest humorist of France, nor Holmes, the prince of American humorists, ever ceased to study medicine. And it is not a little remarkable that in their humorous writings each of them should have dealt with medical matters at times.

Of course, we have all known in a general way that Rabelais was a physician, but few of us, if any, have had the slightest conception of the depth of his thought in physiology, and the profession as a whole stands indebted to Dr. Flint for his very clear exposition of the facts.

founded as it must have been on laborious and painstaking research. It is a notable contribution to the history of medicine.

ARSENIC AS A STIMULANT OF NUTRITION.

THE recent great "epidemic" of chronic arsenical poisoning in England has at least served the good purpose of supplying a large field for the study of the effects of arsenic on healthy persons, and the literature of the drug has in consequence been notably enriched. Among the articles that have appeared, we recall none more valuable than that contributed to the April number of the *British Journal of Dermatology*, by H. G. Brooke, physician to the Manchester and Salford Hospital for Skin Diseases, and Leslie Roberts, honorary dermatologist to the Liverpool Royal Infirmary. These gentlemen deal with the subject systematically, and their article is well worthy of careful study in its entirety. Except for one aspect of it, that in which the action of arsenic on nutrition is considered, our restricted space forbids our attempting to summarize it, although we may call attention to two general statements of interest, namely, that female patients predominated among those who sought hospital treatment, although the women of the lower laboring class in the district consume less beer than the men of the same class, which tends to show that women are more susceptible than men to the action of arsenic; and that the poisonous effects upon the nervous system and those upon the integument were rarely well marked in one and the same individual.

As to the action of arsenic on nutrition, the authors think it stimulates that of certain cells beyond their capability of endurance, so that they perish. They think their observations afford strong evidence in support of the view, put forth by Binz and Schulz, that the physiological effects of arsenic are due to the development of ozone within the system. The arsenic-eating habits of many of the Styrian Highlanders, they remark, afford an excellent instance of the tolerance of arsenic by man. The drug is said to improve the complexion of the women and to maintain the strength and spirits of the men under severe physical exertion. In countries where arsenic is found native, they point out, it has long been customary to administer white arsenic to horses with their food, and, so it is stated, with much benefit to their coats and their general condition. It is added that sheep are reputed to be very tolerant of arsenic. Arsenic kills some micro-organisms, but to others it seems to impart new life. The writers mention the readiness with which

mould fungi grow in a solution of potassium arsenite, a fact which has led to the addition of spirit of lavender in the official preparation. They point also to Giess's observation that young rabbits to which small amounts of arsenic were administered regularly grew to an extraordinary size. The restorative properties of arsenic in certain nervous derangements are well known, and perhaps it may find a place in therapeutics as an actual restorer of tissue elements.

SCARLET FEVER IN THE CAT.

OUR attention is being drawn more and more in recent years to the lower animals as disseminators of infectious disease. Although most writers on comparative pathology doubt the existence of scarlet fever in the cat, observations are occasionally put on record that would lead one to think these authors in error. One of the arguments put forward by the skeptical is this: The domestic cat comes into such intimate contact with its human companions that, if it were susceptible to the disease, it ought often to become its victim. But, says Dr. E. Rapin (*Progrès médical*, May 4th), it may well be that scarlet fever occurs frequently in the cat, but is not recognized. The most noticeable manifestation of the disease in this animal, according to M. Rapin, is loss of the hair. Now, almost everybody regards a cat that is losing its hair as "mangy" and to be got rid of as soon as possible; therefore cats that lose their hair in consequence of scarlet fever are lost sight of without any adequate observation of them having been made. Furthermore, he argues, it may be that only very young kittens are susceptible.

M. Rapin states that in 1894 he showed at a meeting of the Medical Society of Geneva a little white kitten that he believed to be in the desquamative stage of scarlet fever. It was only a few weeks old, and it belonged to a family in which it had been the inseparable companion of two little girls who were suffering from the disease. It was soon seen to be very sick, and for three or four days it gave incessant little plaintive cries and was manifestly feverish, its body being of a burning heat, its skin rosy, and its tongue of a bright red. But the author's attention would not have been attracted to the poor little animal but for its abundant loss of hair, which was much the most pronounced on the posterior parts, so that at one time the kitten looked like a miniature lion. The exposed epidermis looked branny, but there was no positive exfoliation. This kitten finally died.

If we accept the theory that the cat may have scarlet

fever, it seems we must admit that in some instances the new growth of hair that takes place after recovery is of much finer appearance than the original coat. M. Rapin tells us that he once found in the room of a patient to whom he had been called a black and white cat with long and abundant hair of striking beauty. Upon his commenting on the fact, the mistress of the house said: "He took on that fine look after his scarlet fever." And she then gave him the history of her little girl's having had the disease and of the cat's having been evidently ill, and subsequently lost its hair. In this instance the process of desquamation ran a course of several weeks' duration.

In the light of such accounts as these, it may be well for practitioners to be on the lookout for "mangy" kittens in families in which there has been scarlet fever. If such kittens are found, it would be interesting to observe what happens to them and to endeavor to inoculate other kittens from them. But the most important point would be, of course, to prevent them from conveying the disease to susceptible human beings.

THE MUSTARD BATH IN FUNCTIONAL CYANOSIS OF THE NEW-BORN.

IN all probability many a practitioner has resorted to the mustard bath in cases of sudden depression in infants, from whatever cause. Cyanosis, with death imminent, to all appearances, is an accident that sometimes happens to a new-born infant, and that, too, in the opinion of Dr. Adrien Besson, without atelectasis of the lungs or other organic disease. At a recent meeting of the Lille Anatomoclinical Society (*Journal des sciences médicales de Lille*, May 11th) he reported three cases in which the mustard bath had proved promptly efficient and the dangerous condition had not recurred. It is always well to bear simple remedies in mind.

OUR SUBSCRIBERS' DISCUSSIONS.

IN our last issue we published a number of answers to our first monthly prize question, What is the best way of treating the stump of the umbilical cord? By the wide attention paid to the question, as well as by numerous letters that we have received from subscribers, we are assured of the great interest felt in this new department of the *Journal*. The other questions already announced are as follows: What is the best way of prescribing calomel as a purgative (answers due July 10th)? and, How do you treat Colles's fracture of the radius (answers due August 12th)? The following additional question is now announced: Which form of vaccine do you prefer, dried lymph or "glycerinated" lymph? Give your reasons without mentioning producers' names. Answers to this question should reach us on or before September 9th. The conditions of the competition were stated in our issue for May 4th, on page 774, in an article headed Special Notice to our Subscribers.

News Items.

Marine-Hospital Service Health Reports:

The following cases of small-pox, yellow fever, cholera and plague, were reported to the surgeon-general during the week ending June 22, 1901:

Small-pox—United States and Insular.

San Francisco, California.....	June 2-9.....	1 case.	
Key West, Florida.....	June 5.....	1 case.	
Chicago, Illinois.....	June 8-15.....	4 cases.	
Evansville, Indiana.....	June 8-15.....	1 case.	
Michigan City, Indiana.....	June 10-17.....	2 cases.	
South Bend, Indiana.....	June 8-15.....	1 case.	
Clinton, Iowa.....	June 8-15.....	1 case.	
Wichita, Kansas.....	June 8-15.....	3 cases.	
Lexington, Kentucky.....	June 8-15.....	1 case.	
New Orleans, Louisiana.....	June 8-15.....	11 cases.	
Fall River, Massachusetts.....	June 8-15.....	1 case.	
New Bedford, Massachusetts.....	June 8-15.....		3 deaths
Worcester, Massachusetts.....	June 8-15.....	8 cases.	2 deaths
Detroit, Michigan.....	June 8-15.....	33 cases.	1 death
Sault Ste. Marie, Michigan.....	June 16.....	Prevalent.	
Minneapolis, Minnesota.....	June 8-16.....	17 cases.	
Winona, Minnesota.....	June 8-15.....	1 case.	
St. Louis, Missouri.....	June 2-9.....	37 cases.	1 death
Omaha, Nebraska.....	June 8-15.....	12 cases.	
Manchester, New Hampshire.....	June 8-15.....	6 cases.	
Jersey City, New Jersey.....	June 8-16.....	2 cases.	
Newark, New Jersey.....	June 8-15.....	3 cases.	
Plainfield, New Jersey.....	June 8-15.....	1 case.	
New York, New York.....	June 8-15.....	102 cases.	11 deaths
Yonkers, New York.....	June 7-14.....	5 cases.

Marine-Hospital Service:

Official List of the Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days Ending June 20, 1901:

BROWN, B. J., JR., Acting Assistant Surgeon. Granted leave of absence for fourteen days from June 20th.

CORPUS, G. M., Assistant Surgeon. Relieved from duty at the port of St. Louis, June 18, 1901. The leave of absence for one month, granted by the Bureau telegram of May 15th, is amended so that said leave shall be for twenty-one days only.

GARDNER, C. H., Passed Assistant Surgeon. Granted leave of absence for seven days from June 21st.

GOLDSBOROUGH, B. W., Acting Assistant Surgeon. Granted leave of absence for two days.

MOORE, DUNLOP, Assistant Surgeon. To proceed to Port Townsend, Washington, and assume temporary charge of the service during the absence of Passed Assistant Surgeon C. H. GARDNER.

PECKHAM, C. T., Surgeon. Granted extension of leave of absence, on account of sickness, for thirty days from June 20th.

SCHLAAR, W. F., Hospital Steward. Relieved from duty in the Hygienic Laboratory, and directed to proceed to Key West, Florida, and report to the medical officer in command for duty and assignment to quarters.

SCOTT, E. B., Hospital Steward. Granted leave of absence for twelve days from June 24th.

WOODWARD, R. M., Surgeon. Granted extension of leave of absence for three weeks from June 5th.

Naval Intelligence:

Official List of Changes in the Medical Corps of the United States Navy for the Two Weeks ending June 22, 1901:

FURLONG, F. M., Assistant Surgeon. Detached from duty at Guam and ordered to the *Solace* for transportation home.

KEBB, D. B., Assistant Surgeon. Detached from the *Vicksburg* and ordered to the *Culgoa*, and to wait orders en route.

MCCLANAHAN, R. J., Assistant Surgeon. Detached from the *Culgoa* and ordered to the *Vicksburg*.

STOKES, C. F., Surgeon. Ordered to the *Solace*, upon arrival in the United States.

TOLFREE, H. M., Assistant Surgeon. Appointed assistant surgeon from June 14, 1901.

WILLIAMS, R. B., Assistant Surgeon. Ordered to the *Kear-sarge*, June 24th.

Infectious Diseases in New York:

We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending June 22, 1901:

DISEASES.	Week end'g June 15		Week end'g June 22	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	28	8	60	4
Scarlet Fever.....	466	40	362	34
Cerebro-spinal meningitis.....	0	4	0	2
Measles.....	270	8	271	9
Diphtheria and croup.....	244	39	239	42
Small-pox.....	102	11	60	20
Tuberculosis.....	243	141	255	155

Changes of Address.—Dr. Louis A. S. Bodine, from New York to Moriches, N. Y.; Dr. H. A. Slocum, to No. 1900 Chestnut Street, Philadelphia.

Commencement Exercises.—The thirtieth annual commencement exercises of Trinity Medical College, Toronto, were held on June 1st at the University of Illinois Medical School. One hundred and sixty young physicians graduated on May 28th.—The annual commencement of the medical department of the National University, at Washington, D. C., was held on June 7th. There were eleven graduates.—The third annual commencement of Cornell University Medical College, New York, was held on June 5th. There were twenty-six graduates, of whom fourteen were women.

No Exemption of Taxes on Liquor Sold or Given Away in a Hospital.—The Comptroller of the Treasury has approved the decision of the Auditor for the Treasury declining to grant a refund of \$62 paid by the German Benevolent Society of San Francisco as taxes and penalty on the business of a retail liquor dealer, under the war revenue act. The Commissioner of Internal Revenue recommended the refund, and transmitted his recommendation to the auditor, taking the position that the German Benevolent Society conducted a hospital for sick members of the society. He held that it was not a private institution conducted for pecuniary benefit, but a public institution founded and conducted for the general good. It was admitted that wines and liquors were given patients, and in cases charges were made therefor. In passing upon the question the comptroller says that the statute defines a retail liquor dealer as "every person who sells or offers for sale" liquors. It makes no exceptions of hospitals or charitable institutions.

A Health Official Indicted.—Dr. Obed. L. Lusk, deputy sanitary superintendent of the health department in the borough of Queens, was indicted by the Queens County Grand Jury on June 19th on a charge of neglect of duty. The indictment was based on the death of John Charlton of hemorrhagic smallpox at Woodside on May 4th. Charlton's body was left in his apartments, which were in a thickly populated tenement house, for fifty-two hours after death. When the body was finally taken away in an open wagon, his family were driven homeless into the street. It was said that Charlton was ill for several days and that his case was reported to the health authorities, but he was not removed and died while his wife and children stood around his bed, hungry and ill. Besides the indictment against Dr. Lusk, the Grand Jury made a presentment to Justice Maddox, severely criticising the methods in vogue in the Queens health office and demanding that the board of health take immediate steps to stop the scandal in Queens.

The Livingston County (N. Y.) Medical Society has elected the following officers: President, Dr. E. C. Perry; vice-president, Dr. Burt; secretary, Dr. E. A. Sharp; treasurer, Dr. G. G. Jones.

The Clinton County (Ill.) Medical Society recently elected the following officers: President, Dr. W. P. Gordon; vice-president, Dr. T. Gaffner; secretary, Dr. M. Broening; treasurer, Dr. P. H. Leibrick.

The Otsego (N. Y.) Medical Society recently elected the following officers for the ensuing year: President, Dr. A. W. Cutler; vice-president, Dr. A. J. Butler; secretary, Dr. H. W. Boorn; treasurer, Dr. James Burton.

The Dorchester (S. C.) Medical Association has organized by electing the following officers: President, Dr. P. L. Horn; vice-president, Dr. F. Julian Carroll, of Summerville; secretary, Dr. J. B. Johnson; treasurer, Dr. P. M. Judy.

The Buffalo (N. Y.) Academy of Medicine.—The following officers were elected at the recent meeting of the Buffalo (N. Y.) Academy of Medicine: President, Dr. Charles G. Stockton; secretary, Dr. Francis W. McGuire; treasurer, Dr. Charles S. Jewett; trustee, Dr. M. D. Mann.

The Westchester County (N. Y.) Medical Society, which is now nearly 103 years old, has elected the following officers: President, Dr. P. A. Callan, of Yonkers; vice-president, Dr. R. T. Irvine, of Ossining; secretary, Dr. Daisy M. Orleman, of Peekskill; treasurer, Dr. R. T. Howe, of Mount Vernon.

The Harlem Medical Association, at its meeting on June 10th, elected the following officers: President, Dr. Joseph E. Lombard; vice-president, Dr. Edmund L. Cocks; secretary, Dr. W. H. Luckett; treasurer, Dr. W. H. Stewart; trustees, Dr. Montrose R. Richard, Dr. Henry J. Wolf, and Dr. Henry W. Mooney.

The St. Charles County (Mo.) Medical Society has elected the following officers: President, Dr. A. W. Kennison, of O'Fallon; vice-president, Dr. J. T. Evans, of Wentzville; secretary, Dr. A. A. Gossow, of St. Charles. The next meeting will be held in St. Charles on November 9th.

The Society of the Alumni of St. Mark's Hospital.—At a recent meeting of the society the following officers were elected for the ensuing year: President, Dr. Nicholas R. Dann; vice-president, Dr. Conger F. Smith; treasurer, Dr. Ephraim K. Browd; secretary, Dr. Harry G. Watson.

The American Association of Life Insurance Examining Surgeons, at its second annual convention, elected the following officers: President, Dr. James H. Powell, of Chicago; vice-president, Dr. J. H. Reed, of Battle Creek, Mich.; second vice-president, Dr. Talbot Jones, of St. Paul, and secretary-treasurer, Dr. T. A. Stevens, of Caney, Kan.

The Indian Territory Medical Association, at its semi-annual session, elected the following officers for the ensuing year: President, Dr. G. M. West, of Eufaula; first vice-president, Dr. Louis Bagby, of Vinita; second vice-president, Dr. W. E. Harley, of Durant; secretary and treasurer, Dr. Frederick S. Clinton, of Tulsa. The next meeting will be held in Muskogee next December.

The Massachusetts Medical Society celebrated its one hundred and twentieth anniversary in Boston on June 12th. At the business meeting these officers were re-elected: President, Dr. F. W. Draper, of Boston; vice-president, Dr. W. W. Eaton, of Danvers; treasurer, Dr. E. M. Buckingham, of Boston; corresponding secretary, Dr. C. W. Swan, of Brookline; recording secretary, Dr. F. W. Goss, of Roxbury; librarian, Dr. E. H. Brigham, of Brookline.

The Association of Life Insurance Medical Directors has elected the following officers: President, Dr. George S. Shepherd, of Hartford; first vice-president, Edward H. Hamill, of Newark, N. J.; second vice-president, Morris L. King, of New York; secretary, Brandreth Symonds, of New York; treasurer, Frank S. Grant, of New York; executive committee, Edward Curtis, of New York; Oscar H. Rogers, of New York, and Granville M. White, of New York.

The Delaware State Medical Society, at its one hundredth and twelfth annual meeting, elected the following officers: President, Dr. E. S. Dwight, of Smyrna; first vice-president, Dr. Robert Ellegood; second vice-

president, Dr. H. G. Kollock; secretary, Dr. John Palmer, Jr.; assistant secretary, Dr. J. S. Bastian; treasurer, Dr. W. C. Pierce; councillors, for New Castle county, Dr. W. T. Skinner; Kent county, Dr. L. H. Bishop; Sussex county, Dr. W. P. Orr, Jr.

Medical Society of the State of New York.—The president, Dr. Henry L. Elsner, announces the appointment of his business committee for the ensuing year, consisting of Dr. Nathan Jacobson, chairman, 430 South Salina Street, Syracuse; Dr. George Ryerson Fowler, of Brooklyn, and Dr. William C. Krauss, of Buffalo. All letters and inquiries pertaining to papers and scientific communications for the semi-annual meeting, to be held in New York on October 15 and 16, 1901, and the annual meeting, to be held in Albany in January, 1902, should be addressed to the chairman.

The British Congress on Tuberculosis.—The American representative at the British Congress on Tuberculosis, which will be held in London during the week of July 22d, will be Dr. Allen T. Haight, of Chicago, who was sent by the Chicago Medical Society as delegate to the International Otological Congress, which was held in London in August, 1899. Dr. Haight, accompanied by Mrs. Haight, sailed on June 13th. At the congress he will deliver an address on Tuberculosis of the Eye. Many distinguished specialists from various parts of the world will read papers at the sessions of the body, but only the delegates from Great Britain and her colonies will be permitted to take part in the discussions. King Edward and Queen Alexandra will open the congress.

The Fifth International Congress of Criminal Anthropology.—The State Department at Washington has received a note from the minister of the Netherlands stating that the Fifth International Congress of Criminal Anthropology will be held in Amsterdam from the 9th to the 14th of September. The principal questions to be discussed are: First, the anatomical and physiological character of criminals, descriptive studies; second, criminal psychology and psychopathology, criminals and lunatics, theoretical considerations and practical measures; third, criminal anthropology in its legal and administrative application, principles to be followed, preventive measures, protective measures, penalties; fourth, criminal sociology, economic causes of crime, criminality and socialism; fifth, criminal anthropology and ethnology compared. Special questions, such as alcoholism, sexuality, juvenile criminality, senile criminality, hypnotism, criminal psychology in literature, etc., will also be considered.

The Mississippi Valley Medical Association's Meeting: Change of Dates.—It is announced that the dates of the next meeting of the Mississippi Valley Medical Association have been changed from September 10th, 11th, and 12th to September 12th, 13th, and 14th. This change has been made necessary because the dates first selected conflicted with another large association meeting at the same place.

The meeting is to be held at the Hotel Victory, Put-in-Bay Island, Lake Erie, Ohio, and the low rate of one cent a mile for the round trip will be in effect for the meeting. Tickets will be on sale as late as September 12th, good for returning, without extension, until September 15th. By depositing tickets with the joint agent at Cleveland and paying fifty cents the date can be extended until October 8th. This gives members an op-

portunity of visiting the Pan-American Exposition at Buffalo, to which very low rates by rail and water will be in effect from Cleveland.

Full information as to rates can be obtained by addressing the secretary, Dr. Henry E. Tuley, No. 111 West Kentucky Street, Louisville, Ky. Members of the profession are cordially invited to attend this meeting. Those desiring to read papers should notify the secretary at an early date.

A Million Dollars for Harvard Medical School.—J. Pierpont Morgan has agreed to erect new buildings for Harvard Medical School, the estimated cost of which is over one million dollars.

Smallpox.—Incoming ocean and coast steamships still bring an occasional case of smallpox here, while many cases develop in Greater New York. About the city, however, the most alarming conditions are reported from Astoria and Long Island City, where the Queens Borough School Board has decided to close the public schools at both places.—The epidemic has developed in a serious form in the Orange County Jail, at Goshen, N. Y., with the result that the jail has been vacated, the victims being removed to the isolation hospital and the prisoners to the Newburg Jail until danger of infection has passed.—The epidemic is somewhat more prevalent about Greater New York, and especially in Queens County, where the number of cases reported in one day recently was fifty-three. The Grand Jury of that county recently began an investigation at Long Island City into charges that the health officials about Astoria had been lax in their duty in fighting the spread of the disease.—Medical school inspectors of New York city are said to contemplate suing the municipality for their fees for vaccinating about 100,000 public-school scholars, at the rate of \$1 each.—Smallpox has caused the closing of the churches at Plymouth, Pa., while other places where the epidemic has been in evidence lately are Yonkers, N. Y.; Rockland County, N. Y.; Parkersburg, W. Va.; the suburbs of Pittsburgh, Pa.; Bangor, Me., and Wood county, Wis.

Dedication of the Lewis Memorial Hospital.—The Lewis Memorial Cottage Hospital, at New Dorp, Borough of Richmond, which was erected and given to St. John's Guild by Mrs. Frederic Elliott Lewis in memory of her son, Frederick Chandler Lewis, has been formally dedicated. The ceremony was simple, consisting of addresses by William Sherer, president of the guild. The new hospital is intended for the reception of sick babies, and each of the two wards will accommodate eight babies. Only infants that are seriously ill will be received. The building is a wooden structure, 103 feet long and 34 feet 10 inches wide. The cost of building and equipping the hospital was \$10,000.

The Movement for a Hospital for Consumptives in New York City.—The Board of Estimate and Apportionment of New York is seriously considering the advisability of the erection and maintenance by the city of a hospital for consumptives. A member of the board stated recently that there was a probability that the board would take action at some date in the near future and would issue bonds for the erection of the hospital, most likely to be on a site owned by the city. The board would most likely make an appropriation for the relief of consumptives in the budget for 1902, in addition to, or rather apart from, the appropriation allowed for the present year to private and semi-private institu-

tions. For this year the city of New York has set aside the sum of \$70,010 for the maintenance of the consumptive poor. Of this amount, the Brooklyn Home for Consumptives received \$6,000; St. Joseph's Hospital, One Hundred and Forty-third Street and St. Ann's Avenue, \$34,010, and Seton Hospital, in the Bronx, \$30,000. St. Catharine's and St. Peter's hospitals, Brooklyn, care for consumptives, but receive no special fund from the city. Last session the legislature appropriated \$50,000 for a site for a Consumptive's State Hospital, and this coming session it is expected that \$100,000 will be appropriated for buildings and maintenance. It is not believed that the city could build as cheaply, but taking the \$70,000 annually appropriated heretofore into account, the additional expense would not be great.

A Big Sanitarium Planned for Chicago.—Details are under consideration for the construction of a magnificent hotel and sanitarium in Chicago at a cost of \$400,000. The ground is owned by the Chicago University and fronts forty feet on the boulevard, with a depth of one hundred and sixty feet on the court. Among those who are interested are five of the leading physicians and surgeons of Chicago, including Dr. J. B. Murphy, Dr. Franklin H. Martin, Dr. Phineas I. Mulvane, Dr. Frank Billings, and Dr. Nicholas Senn. It is proposed to lease the ground for ninety-nine years. Plans have been completed for an eight-story building, on which construction will be commenced as soon as the details are arranged.

Hospital Buildings and Endowments.—The work of laying the foundations of the new hospital being built by the Sisters of St. Francis at Louisville, Ky., has been begun.—By the compromise of the will of Julius Adams, of Boston, the Carney Hospital, of that city, receives bequests of \$56,250.—The children of Jacob and Hannah Rosenberg, of Chicago, have added \$25,000 to the funds of the Michael Reese Hospital, of that city. The money will probably be made the basis of a fund for a new hospital building.—The contract has been awarded for the erection of the Frederick City Hospital, at Frederick, Md., at a cost of about \$8,000.—The new La Crosse (Wis.) Hospital, completed at a cost of \$50,000, was formally opened on May 14th.—The managers of the Free Hospital for Consumptives, Philadelphia, have bought land near White Haven, on the banks of the Upper Lehigh River, as a site for a sanatorium. It is expected that the State will appropriate \$50,000 for the institution. Cottages will be erected on the site so soon as money can be obtained. Patients are cared for under a special arrangement in several local hospitals.—The cornerstone of the new Jewish Hospital, to be erected in St. Louis, was laid with appropriate ceremonies on May 16th.—An agitation has been started for the establishment of a State hospital in Jackson, Miss., to be supported by legislative appropriation.—The New York Municipal Council has passed a resolution appropriating \$7,000 for the construction of an emergency hospital at Coney Island.—Active work will soon be begun on a new hospital building to cost \$40,000 and to take the place of the Peninsula General Hospital at Salisbury, Md.—The Bethesda Hospital at Cincinnati, Ohio, was dedicated on May 16th.—The contract for building the Charlotte Williams Hospital, Richmond, Va., has been awarded. The hospital will probably cost about \$150,000.—Henry Hawthorne has not word that he will aid in building the new Hospital

for Incurables, in Albany, N. Y.—A site has been selected for the new Presbyterian Hospital at Atlanta, Ga.—The cornerstone of the new St. Anthony's Hospital, at Louisville, Ky., was laid on June 2d.—The following appropriation bills were recently passed in the Pennsylvania legislature: Pennsylvania Epileptic Hospital, \$10,000; Rush Hospital, Philadelphia, \$10,000; Adrain Hospital, \$30,000; Gyneccean Hospital, Philadelphia, \$20,000; Kensington Hospital, Philadelphia, \$5,000; Altoona Hospital, \$15,000; St. Vincent's Hospital, Erie, \$10,000; Eye, Ear, Throat, and Nose Hospital, Pittsburgh, \$3,000.—A chapel, capable of seating 300, is being added to the General Hospital at the Presidio, San Francisco.—The will of Joseph Corbit, of New York, gives \$2,000 to the Presbyterian Hospital, of that city.—The State Commission in Lunacy has approved the plans for a new group of buildings at the Rochester (N. Y.) State Hospital, to cost about \$230,000. This will afford accommodations for 500 patients.—The general synod of the Lutheran Evangelical Church, of St. Paul, Minn., will finance a new thirty-bed non-sectarian hospital, to be opened about September 1st. A building and lot have been purchased for the purpose and the plans contemplate future additions as the institution prospers.—The cornerstone of the County Consumptive Hospital, at Buffalo, N. Y., was laid on May 31st.—Ground has been broken for the new hospital at Frederick, Md.—By the will of Dr. Marie J. Mergler, of Chicago, the Woman's Hospital, of that city, receives \$3,000.—The municipal authorities of St. Paul, Minn., are to add a new contagious ward to the city hospital at a cost of about \$25,000.—An addition to the German Hospital, at Chicago, to cost \$40,000, is planned. The hospital now has accommodations for one hundred patients, and there is a demand for double the quarters available.—A Jewish hospital, to be known as the Mt. Sinai Hospital, will be erected in Boston. Several thousand dollars have already been subscribed.—James K. Mosser, of Allentown, Pa., has given \$35,000 to pay for the erection of a wing to the Allentown Hospital.—Contracts for the hospital building to be erected in connection with the State Institute for Defectives at Faribault, Minn., have been let.—The new Franklin Hospital, at Boston, was formally opened on June 6th.—The navy's new hospital, at Yokohama, is nearly completed, and a letter to Surgeon-General Van Reypen, at Washington, D. C., says that the building is greatly admired. The Japanese Government has given a lease in perpetuity for the site occupied by the hospital.—The new addition to St. Luke's Hospital, at Racine, Wis., was dedicated on May 31st with appropriate exercises. The building cost about \$10,000.—The sum of \$56,000 has been subscribed toward the erection of a new private hospital at Kansas City, Mo.—The Charles Hitchcock Hall of the University of Chicago, the cornerstone of which will shortly be laid, and which will cost \$150,000, will contain a hospital.—By the will of Mrs. Matilda B. Brown, of New York city, St. Vincent's Hospital is bequeathed \$2,500.—Ground was broken, on June 12th, for the extensive additions to the Providence Hospital, at Washington, D. C. The estimated cost is about \$250,000.—An extension, 34 by 50 feet, three story and basement, is to be added to the building of St. Mary's Free Hospital for Children, at No. 407 West Thirty-fourth Street, New York. The annex will be occupied by additional wards and will have a handsome chapel. The improvements are to cost \$45,000.—The will of Dr.

W. S. Caldwell provides that the Provident Hospital, of Chicago, shall receive the residue of his estate, estimated at \$50,000. St. Francis Hospital, of Freeport, Ill., receives \$10,000.—A civil hospital is to be established, partly by subscription and partly by government appropriation, on the island of Guam.—John Sweetzer, of Boston, has bequeathed \$25,000 to the New England Hospital for Women and Children, following the death of his brother and sister, who are to enjoy the income meanwhile.—Mrs. Lewis H. Hyde, of New York, has contributed \$5,000 to the erection of the Winchester (Va.) Memorial Hospital and will also endow two memorial beds in the institution.—The cornerstone of the new Borgess Hospital, at Kalamazoo, Mich., was laid on June 9th.—The trustees of the German Hospital, a semi-charitable institution maintained by the German Lutheran churches of Chicago, have decided to enlarge the present hospital building by an addition of seventy-five feet front. The improvement will cost \$40,000.—The new Presbyterian Hospital, at Atlanta, Ga., will be formally opened on July 1st.—The contract for the erection of the proposed Charlotte Williams Hospital, at Richmond, Va., has been let, and work will shortly be begun. The contract calls for the completion of the hospital by July 1, 1902. The hospital will be the largest institution of its kind in the South, with the exception of the Charity Hospital, of New Orleans.—Steps are being taken to enlarge the Denver (Col.) Jewish National Hospital for consumptives. At present the hospital accommodates sixty-three patients, at an annual cost of \$26,000. When the new building is completed twice as many patients can be received, the estimated annual cost of maintenance being \$60,000.—Two new wings are to be added to the Gowanda (N. Y.) State Hospital at a total cost of \$150,000. Provision has been made in past appropriations by the legislature.—The General Hospital at the Presidio, San Francisco, which was damaged to the extent of \$30,000 by fire on June 10th, will be rebuilt immediately.—The Wesley Hospital, Chicago, recently completed at a cost of \$210,000, was informally opened on June 17th.—The cornerstone of the new Hospital of St. Mary, to be erected by the Sisters of the Family of Nazareth, at Chicago, was laid on June 16th. The building will cost more than \$200,000 and will be finished within two years.—The laying of the cornerstone of St. Mary's Sanitarium, at Fond du Lac, Wis., took place on June 12th. Archbishop Katzer and priests from the various cities of the diocese were in attendance, together with the resident physicians, prominent citizens, and the Sisters of St. Agnes. The sanitarium is the gift of John T. Boyle, and is to be one of the finest in the Northwest, costing \$50,000 complete.

The Death of Mr. Thomas Bond, F. R. C. S., took place in London early this month. Mr. Bond was one of the most prominent medico-legal experts in England, and has been concerned in most of the *causes célèbres* of recent years in England. He was also a recognized authority on railway injuries.

In Memory of Dr. Lazear.—A tablet to the memory of the late Dr. Jesse William Lazear, of Baltimore, who died from the effects of yellow fever contracted while experimenting on its communicability, was unveiled on June 18th, at the Trinity Hall Military School, Washington, Pa., of which institution he was an alumnus. Dr. Lazear graduated from Johns Hopkins University,

and took his medical degree at the College of Physicians and Surgeons, New York, and subsequently studied abroad. While serving as assistant surgeon in the United States Army, he was detailed to serve on the yellow fever commission. He volunteered to permit yellow-fever-infected mosquitoes to sting him, and became thereby infected and died, a martyr to science.

Births, Marriages, and Deaths.

Married.

ARCULARIUS—DU BUISSON.—In Montclair, N. J., on Wednesday, June 19th, Dr. Philip Edward Arcularius, of New York, and Miss Marie Fernine Du Buisson.

CLARK—KELLY.—Kosciusko, Mississippi, on Wednesday, June 12th, Dr. Clifton Power Clark, of Washington, and Miss Alta Kelly.

DROHAN—SAXTON.—In Brockton, Massachusetts, on Wednesday, June 19th, Dr. James H. Drohan and Miss Margaret L. Saxton.

FLOYD—DELAFIELD.—In Riverdale, N. Y., on Thursday, June 20th, Dr. Rolfe Floyd, of New York, and Miss Emily Delafield.

HERTEL—HARTNAGEL.—In Belleville, Illinois, on Wednesday, June 19th, Dr. H. G. Hertel and Miss Lulu Hartnagel.

HOWARD—MORRISON.—In Salem, N. J., on Thursday, June 20th, Dr. A. L. Howard, of Washington, and Miss Anna R. Morrison.

HUMPHREY—BARBER.—In Warsaw, N. Y., on Thursday, June 20th, Dr. L. Hayden Humphrey, of Silver Springs, N. Y., and Miss Martha Barber.

JOHNSON—TAYLOR.—In Washington, on Wednesday, June 19th, Dr. Henry L. E. Johnson and Miss Eugenie Taylor.

JONES—TRIPP.—In New York, on Wednesday, June 19th, Mr. Joseph J. Jones and Miss Susan E. Tripp, daughter of Dr. William J. Tripp.

LEE—PIERSON.—In Jersey City Heights, on Tuesday, June 18th, Dr. Stephen G. Lee, of East Orange, N. J., and Miss Laura M. Pierson.

LEWIS—WEIL.—In New York, on Thursday, June 20th, Dr. William G. Lewis, of Albany, and Miss Emma Weil.

MANN—FULTON.—In York, Pennsylvania, on Wednesday, June 19th, Dr. E. S. Mann, of Philadelphia, and Miss Mary A. Fulton.

MANN—SCOTT.—In Petersburg, Virginia, on Wednesday, June 19th, Dr. John Mann and Miss Nannie Scott.

MATLACK—JACKSON.—In Sedalia, Missouri, on Sunday, June 9th, Dr. James A. Matlack, of St. Louis, and Miss Edith Jackson.

MERCER—MORRISON.—In Virden, Illinois, on Wednesday, June 19th, Dr. William Harvey Mercer and Miss Grace Greenwood Morrison.

NOURSE—WINDSON.—In Darnestown, Maryland, on Wednesday, June 19th, Dr. W. D. Nourse, of Dawsonville, Maryland, and Miss Alice Windson.

SANDERS—WILKINS.—In Rochester, on Tuesday, June 18th, Dr. Llewellyn J. Sanders and Miss Grace Wilkins.

SCHWILK—MORSE.—In Albany, on Wednesday, June 19th, Dr. E. T. Schwilk and Miss Elizabeth Morse.

STEWART—LANGWORTHY.—In Pittston, Pennsylvania, on Saturday, June 22d, Dr. William Alvah Stewart, of Washington, and Miss Julia Elizabeth Langworthy.

STRONG—STONE.—In Swanton, Vermont, on Wednesday, June 12th, Dr. Chapman Edward Strong, of Astoria, N. Y., and Miss Florence Mary Stone.

Died.

ATHEY.—In Holly Springs, Mississippi, on Thursday, June 20th, Dr. J. Howard Athey, in the sixty-sixth year of his age.

BARTON.—In Alexandria, Virginia, on Wednesday, June 19th, Dr. Mary Barton, in the fifty-fifth year of her age.

GROSS.—In Black Rock, N. Y., on Tuesday, June 18th, Dr. Edward L. Gross.

HUDSON.—In Brooklyn, on Thursday, June 20th, Dr. William T. Hudson, in the fifty-ninth year of his age.

REYNOLDS.—In Pittsburgh, on Wednesday, June 12th, Dr. Benjamin F. Reynolds, in the sixty-seventh year of his age.

WAITE.—In New Bedford, Massachusetts, on Thursday, June 20th, Dr. E. E. Waite, in the forty-third year of his age.

WOODS.—In Abbeville, Louisiana, on Friday, June 14th, Dr. Lee Woods, in the forty-fifth year of his age.

Pith of Current Literature.

Medical Record, June 22, 1901.

Hernia of the Urinary Bladder. By Dr. W. S. Cheesman.—The author's conclusions are: (1) The principal cause of bladder hernia is direct traction exercised through the peritoneal coat by the weight of the hernial mass, or by pulling on the sac during ligation in operating for radical cure. (2) In one sixth of the cases symptoms occur sufficient to arouse suspicion, sometimes amounting to certainty, of the existence of the abnormality. (3) In about one fourth of the cases it may be possible during operation to recognize the bladder and to avoid injuring it; and after one hernial sac has been found, any structure resembling a second should be regarded as bladder until proved otherwise. (4) When the bladder is wounded, the best procedure is immediate suture by two layers of catgut, and closure of the hernial wound by Bassini's method; a small drain only being left leading to the bladder suture line. The bladder wall, when thinned, may be freely resected preparatory to closure. The catheter *à demeure* is not essential to primary union of wounds thus closed. (5) Urinary fistula nearly always closes spontaneously. (6) Injuries of the bladder have been directly responsible for death in only ten per cent. of the hernia cases in which they have occurred.

The "Nauheim Treatment." By Dr. H. Newton Heineman.—According to the author, no form of treatment in the range of medicine can show a larger number of improved patients. Failure to achieve the desired improvement sometimes results from the patient's indifference or inability or badly advised course in not repeating the treatment during the succeeding year. The author warns against the natural inclination to increase too rapidly the strength of the treatment in some cases, even upon subsequent visits or courses of treatment. The increasing severity must be determined by experience and a careful weighing in the given case of the probable after-effect as well as the immediate result. Experience alone can determine whether in a given case further improvement is best secured by a continuation of the same warm bath, or whether the simple general tonic effect of a cooler bath would add to the result. But the distinction between such kinds of treatment should always be kept clearly in mind, if increasing experience is ever to lead to definite scientific conclusions. A few cases are given.

On Nephrorrhaphy with Flap Fixation. By Dr. Arnold Sturmdorf.

The Boston Medical and Surgical Journal, June 20, 1901.

A Study of the Food Consumed and Digested by Four Members of the Harvard University Boat Crew in June, 1900. By W. O. Atwater and F. G. Benedict.—That athletes eat considerably more than people in ordinary life is what would naturally be expected. An especially interesting feature of the food of the athletes is the much larger amount of protein in proportion to the fuel value than is found in the food of people with ordinary muscular strain; that is to say, in increasing their food over the ordinary consumption, the athletes added much more proportionally to the protein than to the other nutrients (fats and carbohydrates). Why and to what extent this large proportion of protein represents a physiological necessity is not yet fully known. To the authors, however, it seems very natural that where great muscular strength and effort are needed, there should be corre-

sponding muscular development, and this would be most naturally attained by the use of nitrogenous food. (*To be continued.*)

Puerperal Insanity. By Dr. Edward B. Lane.—The author objects to the use of the term "puerperal insanity" to define a distinct type of mental trouble, as he does not find any such in practice. A nomenclature not based on mental symptoms alone leads to hopeless confusion and is most unscientific. From an examination of Boston statistics, he arrives at the very interesting result that, as a matter of fact, insanity associated with child-birth occurs only half as often as it does among women in general at the child-bearing age.

The Home Treatment of Tuberculosis versus the Climatic Treatment. By Dr. Edward O. Otis.—As it is the very small minority who are willing or able to travel far afield for a resort in which to take the cure, and the majority, for one reason or another, must, if the hygienic cure is attempted at all, undertake it at home, the author believes it a source of gratification that the prospects of success in the home treatment appear so auspicious.

A Case of Marked Cyanosis, Difficult to Explain. By Dr. Sylvester F. McKeen.

Medical News, June 22, 1901.

Psychic Epilepsy, with the Report of a Case. By Dr. J. W. Courtney.—By psychic epilepsy we understand those peculiar pathologic alterations of consciousness and memory which may precede, accompany, follow, or even take the place of the epileptic fit. The exceeding infrequency with which the opportunity to personally observe an attack occurs, is the author's reason for this paper, in which a case is given in great detail.

The Medical Expert Evidence in the Case of the Davis Bellevue Hospital Homicide. By Dr. R. L. Pritchard.—The author takes issue with the district attorney and asserts emphatically that medical expert testimony is *not* a race among liars, with the case in question as an instance. He shows that medical expert testimony is more often defective from the manner of its presentation than from an assumed yielding of the expert witness to whatever opinion is desired of him. The medical expert who makes the possibilities of medical science his excuse for almost any opinion demanded of him, is not found in a trial of great public interest, where the medical witnesses are the foremost members of the medical profession.

Obstipation. By Dr. Sterling B. Taylor.—The author deals particularly with obstipation arising from hypertrophy of the normal rectal valves; with consequent interruption of lumen of canal and accompanying distention of gut above obstruction, the latter condition begetting an atonic state. Such a condition begets "classic" symptoms which the author enumerates: (1) Chronic irregularity of bowel movement; (2) frequent partially successful attempts to evacuate the bowels; stool flattened laterally; (3) an inordinate desire for successful defecation; (4) a feeling of distention over the course of the colon, more marked in the descending segment and at the colosigmoidal angulation; (5) inability to pass gas freely; (6) mucus—clear, dirty, or sanious in character; (7) evidence of self-intoxication. The radical treatment consists in division of the free border of the valve, or valves, affected. The operation is one of great delicacy. Palliative treatment in the shape of massage, enemata, diet, etc., is of some value.

A Study of some Complications and Sequelæ of Typhoid Fever. By Dr. H. A. Hare and Dr. H. R. M. Landis. (*To be concluded.*)

Journal of the American Medical Association, June 22, 1901.

The Cause of Diffuse Peritonitis Complicating Appendicitis, and its Prevention. By Dr. A. J. Ochsner.—The Chairman's address at the opening of the Section on Surgery and Anatomy at the St. Paul Meeting. See *New York Medical Journal*, June 8th, p. 1011.

The Address of the Chairman of the Section in Obstetrics and Diseases of Women at the St. Paul Meeting. By Dr. Henry P. Newman.—Will be abstracted in the report of the proceedings of the Section, in a forthcoming number.

Oral Manifestations and Allied States. By Dr. E. S. Talbot.—In this paper on scurvy, the author demonstrates the utility of the lower animals for its study. It is particularly frequent in dogs, and the description of the dental conditions found in these animals in this disease is interesting. The bacteriology of scurvy and the bacteria of pyorrhœa alveolaris are considered and the results of inoculation experiments are given. The article, which is illustrated, is to be continued.

Anthrax, with Report of a Case. By Dr. William Roush.—This case is interesting as confirming the experience of Vockresensy that the use of large doses of carbolic acid internally in this affection. He (Vockresensy) asserts that he has cured sixteen consecutive cases of malignant pustule, and in some the use of carbolic acid was not begun until the seventh day. In the author's case, though the carbolic acid was not used until the eighth day, improvement was noticeable within twenty-four hours.

Interesting Throat Paralysis in a Case of Locomotor Ataxia of an Irregular Form. By Dr. John Edward Rhodes.

The Diagnosis of Diaphragmatic Hernia. By Dr. E. Fletcher Ingals.

The Value of Calcium Carbide in the Treatment of Inoperable Carcinoma of the Uterus. By Dr. I. C. Chase.—In the author's opinion, acetylene has no effect on protoplasm sufficient to support a theory of any specific annihilative action on carcinomatous cells. It has no escharotic effect. It has no bactericidal action upon pathogenic bacteria or upon the bacteria of putrefaction. The principal action of calcium carbide results from liberated quicklime. Lime is not a rational caustic to select because of its superficial action, the character of the necrosis, and the tendency to promote hæmorrhage. The metallic salts are more styptic, and their action may be better graduated by proper selection. The amount of heat evolved may be sufficient to slightly cauterize the tissues. In most cases it has slight therapeutic effect save counteracting the tendency to hæmorrhage and promoting contraction. The heat of the actual cautery promises better results. Calcium carbide is open to the same dangers as other caustics when improperly or too zealously applied. The treatment does not reduce odor or hæmorrhage or give more comfort to the patients than other rational lines of treatment. In fine, there is no evidence in theory or practice warranting the conclusion that calcium carbide could ever cure a case of really inoperable cancer of the uterus.

Morphinism: An Unusual Case. By Dr. Wesley E. Taylor.—The cure of the habit in this case was accom-

plished by the patient *alone*. The habit was of long standing, and thirty grains a day were necessary for the patient's comfort. The use of the drug was stopped, absolutely and at once. The author suggests that it might be advisable to break away from the rule of a gradual diminution of dose, and he does not see why some of the burden should not thus be put upon physical, instead of all on the mental, resistance.

Spasm of the Glottis and Oesophagus in Adult Life. A Report of Two Cases. By Dr. L. D. Brose.—The author lays stress upon the possibility of such symptoms being due to pressure on the recurrent laryngeal and oesophageal nerves; and advises that a diagnosis be not arrived at until such pressure has been most carefully excluded.

Magnetic Foreign Bodies in the Eye. By Dr. E. Villiers Appleby.

The Importance of Instruction in Medical Schools upon the Modification of Milk for Prescription Feeding. By Dr. Andrew H. Whitridge.

A New Proctoscope and Sigmoidoscope. By Dr. William M. Beach.

Philadelphia Medical Journal, June 22, 1901.

Further Notes of a Case of Pernicious Anæmia Reported at the Meeting of the Association of American Physicians in 1900; with Remarks on the Diagnosis of the Disease. By Dr. Frederick P. Henry.—The diagnosis of pernicious anæmia is most firmly based upon the *tout ensemble* of signs and symptoms, both positive and negative. The presence of megaloblasts is confirmatory of, but not indispensable to, the diagnosis. They possess a prognostic, rather than a diagnostic, value, for they often appear in the blood in large numbers shortly before death, and are frequently absent for months during periods of remission. With reference to the statement that cases of anæmia with a hæmic unit of twenty-five, and a hæmoglobin percentage of thirty, are not rare and that they often end in recovery, the author states that during a continuous service in large hospitals for seventeen years, during which time he has been on the alert for cases of pernicious anæmia and conditions resembling it, he has had no such experience.

A Case of Severe Anæmia with Changes in the Spinal Cord. By Dr. William E. Hughes and Dr. William G. Spiller.

The Teaching of Chemical Pathology. By Alonzo Englebert Taylor.—It will never be possible to take each student over the whole field, just as it is not possible to give each student work in all the lines of physiology or to demonstrate all the lesions of morbid anatomy. The author does not believe it is necessary, for, if each student *works* through, and *thinks* through, a few of the conditions of disease, the mental training and the grasp upon the subject thus attained will be of high value, above and beyond the training in diagnosis. As for the latter development of the student's medical mind, the chief object of the course should be to teach the student to view disease as much from the functional as from the anatomical point of view, to correlate in his mind morbid physiology with morbid anatomy, and to carry this association into practical and original work.

Theoretical and Practical Considerations on the Treatment of Jacksonian Epilepsy by Operation; with the Report of Five Cases. By Dr. James Jackson Putnam. (*Concluded.*)

What I have Learned from One Hundred and Sixty-one Operations for the Relief of Senile Hypertrophy of the Prostate Gland. By Dr. Orville Horwitz. (*Concluded*).—From his results, the author sets forth the following conclusions: (1) Success following the Bottini operation depends on having perfect instruments; a good battery; the necessary skill, and the employment of a proper technique. (2) In suitable cases the Bottini is the safest and best radical operation thus far advised for the relief of prostatic hypertrophy. (3) It is often very efficacious in advanced cases of obstruction as a palliative measure, rendering catheterism easy and painless, relieving spasm, lessening the tendency to constipation, and improving the general health. (4) It is of special service in the beginning of obstructive symptoms due to hypertrophy of the prostate gland, and may be regarded as a means of preventing catheter life. (5) It is indicated in all forms of hypertrophy except where there is a valvular formation, or where there is an enormous overgrowth of the three lobes, associated with tumor formation giving rise to a pouch, both above and below the prostate gland. (6) Where the bladder is hopelessly damaged, together with a general atheromatous condition of the blood vessels, associated with polyuria, results are negative. (7) Pyelitis is not a contra-indication to a resort to the operation. (8) The character of the prostatic growth has no bearing on the results of the operation.

American Medicine, June 22, 1901.

The Treatment of Abdominal Aortic Aneurysm by a Preliminary Exploratory Cœliotomy and Peritoneal Exclusion of the Sac. Followed at a Later Sitting by Wiring and Electrolysis, with the Report of Two hitherto Unpublished Cases. By Dr. Rudolph Matas. (*To be concluded*).—To the author it is evident that there are many fallacies and unavoidable sources of danger in abdominal aneurysm which distinctly preclude the possible success of the method in a large proportion of the cases, no matter how perfectly the technique may be carried out. Notwithstanding all the advantages of an exploratory laparotomy, many of the essential points in the diagnosis, such as the exact origin of the aneurysm, the part of the aorta in which the aneurysmal orifice is situated, the size of the orifice, the relation of important visceral branches to the sac, the condition of the walls of the sac, etc., must remain unknown. We really know nothing positively of what this procedure will accomplish in the living subject except, perhaps, the empiric and gross fact that the method has been instrumental in saving the lives of three out of fifteen recorded cases of abdominal aneurysm. It is not universally applicable, and it is much less justifiable in some cases than in others. Under these circumstances some effort should be made to define the indications for or against this operation in this class of cases.

The so-called Traumatic Neurosis. By Dr. Harold N. Moyer.—The author puts forth the following points for discussion: That concussion-neurosis, in all its various appellations, is an unfortunate and misleading term; that clearer understanding of functional nervous trouble renders such a term unnecessary; that pain and tenderness of the spine is rarely an evidence of change in the cord, but is usually due to fatigue of the spinal muscle, or to sprains and concussions of the column; that most of the symptoms of spinal concussion, as the term is commonly used, are cerebral in origin, and that a correct diagnosis and prognosis may usually be reached by

analyzing all such cases in the same manner that we do functional nervous troubles having their origin in non-traumatic causes.

Resection of Superior Sympathetic Cervical Ganglion for Non-inflammatory Glaucoma. By Dr. Joseph Mullen.

The Bacteriologic Examination of Clinical Thermometers. By Dr. Randle C. Rosenberger.—It is possible for the thermometer to be laden with the usual flora of the oral cavity, and such bacteria may retain their capability of growth for an indefinite time—at least two months. Many pathogenic bacteria possess similar capabilities, and it is not unreasonable to assume that the transmission of bacterial disease by the thermometer is possible. Thermometers are easily disinfected, but, when possible, each patient should possess a thermometer as much his own property, and as sacred to his own use, as his toothbrush.

A Typical Pneumonia and Pulmonary Tuberculosis. By Dr. W. H. Bergtold.—The author is always suspicious of an atypical pneumonia and he believes that every such case should be suspected and put under surveillance until proved not to be tuberculous, and there is little excuse for allowing cases to go many weeks, even days, unrecognized.

Electrolysis in Diseases of the Skin. By Dr. F. E. Wisecup.

The Nervous Exhaustion Due to West Point Training. By Dr. Charles E. Woodruff.

Lancet, June 15, 1901.

The Chemical Side of Nervous Activity. (*Abstract*). By Dr. W. D. Halliburton.—The first and second of the Croonian lectures for 1901. Will be abstracted on completion.

Standardization of Calmette's Antivenomous Serum with Pure Cobra Venom: The Deterioration of this Serum through Keeping in India. By G. Lamb, M. B., and W. Hanna, M. B.—The authors report the results of a number of experiments bearing upon the standardization of antivenomous serum, and its deterioration in warm climates. They find that more serum is required to neutralize pure cobra venom than has hitherto been supposed. The dose of serum to be injected in cases of cobra bite depends upon factors which cannot be directly experimentally determined—namely, (1) upon the amount of poison the snake has injected and (2) upon the amount of cobra venom which an average man can survive. In view of the fact, however, that in the treatment of any case of cobra bite we must always estimate the dose of antivenine to meet the possibility of the snake having injected the maximum quantity of poison possible, a dose of from 30 to 35 cubic centimetres of fresh serum, or its equivalent, should be given in every case. Their experiments show that antivenomous serum undergoes a progressive and fairly rapid deterioration when stored in hot climates, and that this deterioration is greater and more rapid the higher the mean temperature to which it is subjected. Tables are given which show the neutralizing power of various specimens of serum of different ages and sources of supply.

The Feeding of Diphtheria Patients, with Special Reference to Children and Severe Cases. By Dr. R. G. Kirton.—Feeding in diphtheria may be carried out by (1) the mouth; (2) the nasal tube; (3) the rectum; and (4) subcutaneous injections. Although mouth feeding is the best, certain conditions render it impossible or in-

divisible. Among these are: (1) inability to swallow due to pain or swelling; (2) regurgitation; (3) entrance of food into the larynx, indicated by persistent coughing after feeding; (4) struggling and the consequent exhaustion; and (5) continued vomiting—(a) present from the onset of the disease; (b) early vomiting from the second week; and (c) late vomiting. In the early stages of diphtheria milk should be the chief food. Children with regurgitation should be fed very slowly, and the quids given should be thickened. Where vomiting occurs the food should be given in small quantities and more often; should the vomiting persist other modes of feeding should be substituted. Brandy is preferable to whiskey where a stimulant is indicated, as it is less apt to cause vomiting. The following conditions render nasal feeding advisable: (1) inability to swallow from regurgitation or paralysis; (2) coughing on feeding; (3) cases where vomiting occurs on mouth feeding, but not with feeding by the nose; (4) exhaustion; and (5) local effect. All foods should be strained, measured, and given warm. It is occasionally necessary to use a siphon tube instead of the ordinary soft rubber one. Recurrent alimentation should be resorted to when feeding by the mouth or nose fails or is insufficient. It is required here there is (1) vomiting; (2) great difficulty in passing the nasal tube; (3) harmful action of nasal feeding from fright, struggling, etc.; and (4) epistaxis caused by passage of the nasal tube. A funnel and soft rubber tube should be used; never a ball syringe, as it is impossible to regulate the pressure. The feedings should have as their basis peptonized milk, and often this is their only constituent. Raw meat juice, white of eggs, and occasionally the yolks of eggs, may be added. The amount depends upon the age of the patient; it should be given warm about every four hours. The bowels should be washed out every twenty-four hours to prevent diarrhoea, which is a troublesome and serious complication in these cases.

In addition to these forms of administering food, the injection of sterile horse serum into the subcutaneous tissues is to be recommended. From twenty to forty cubic centimetres are as much as it is advisable to inject daily. The only indication against the use of these injections is hæmorrhage into the subcutaneous tissues adjoining the site of injection. Transient rashes have occasionally been observed. In conclusion, the author reports four cases of diphtheria in which the feeding was a serious and important question, and gives a long table showing the amount, nature, and method of administration of food in one especially difficult and severe case.

Scarlatinal Infection: An Inquiry and an Illustration. By J. B. Pike, M. R. C. S.—The author suggests the possibility of scarlatinal infection being carried by the pus from a middle-ear discharge. Certainly the middle ear and mastoid cells form excellent quarters for the germs to lie quiet in. If they can do so for a long indefinite time, our view of the infective period of scarlet fever must be enlarged. Another interesting question is whether a secondary self-infection is possible from scarlatinal poison lurking in the cavities of the temporal bone. The author reports a very interesting case of scarlet fever which illustrates the possibility of these suggestions.

Pure Urea in the Treatment of Tuberculosis. By R. H. Harper.—The author records his further experience of the use of pure urea in the treatment of pulmonary tuberculosis, and reports five cases in which its use was followed by the greatest improvement. Urea in-

creases the toxicity of the body tissues and fluids toward the tubercle bacillus, thus acting as an antitoxine. There is a natural antagonism between gouty diseases and tuberculosis, and gouty patients possess a natural antitoxine against the tubercle bacillus. Numerous other examples are given to show the relative antagonism between tuberculosis and conditions where the amount of urea in the system is increased.

Sulphur in the Treatment of Dysentery. By Dr. G. E. Richmond.—The author reports two cases of dysentery in which the administration of twenty grains of sublimed sulphur combined with five grains of Dover's powder, every four hours, brought about rapid recovery. The discharge of blood and mucus quickly stopped, and the movements became fecal. The sulphur seems to act as a strong antiseptic and brings about a speedy healing of any ulcerated surfaces in the intestine. So far the author has not had a single failure in the treatment of dysentery by this method.

The Practical Choice of Climate in Phthisis. By Dr. W. Gordon.—After certain preliminary considerations of his subject, and after enumerating those cases of phthisis in which the patient should be kept at home, the author classifies the patients who should be sent away as follows: (1) Early, uncomplicated cases should go to the Swiss Alps, of which Davos may be taken as a type. (2) Early cases with recurrent hæmorrhages, and (3) early cases which have originated in pleurisy or pneumonia, should also be sent to the Alps. (4) Early cases in weakly persons, if they do not feel cold easily, should also go to the Alps, or to Egypt, the Riviera, or to Nordrach. (5) Post-influenzal cases with considerable irritation do well at the Riviera. (6) Catarrhal phthisis does well at Madeira. (7) Cases of scrofulous or (8) fibroid phthisis may be sent to the Riviera. (9) Bronchiectatic phthisis does best at the Riviera. (10) In phthisis with emphysema, Egypt or the Riviera should be selected. (11) Laryngeal phthisis does best at San Remo or Mentone. (12) Elderly patients winter best in Egypt; (13) cretanic patients do well there also. (14) Anæmic patients and (15) those with heart or arterial disease should choose the Riviera.

The author, of course, looks at these various resorts from the point of view of their accessibility from England. He speaks highly of Colorado and Southern California. As to sea voyages, any advantage as to fresh air, etc., is outweighed by the disadvantages to an invalid at sea. Foreign climates for the poor are practically non-existent. Sanatoria do not supersede climatic treatment.

Four Cases of Perforation (Gastric and Duodenal) Successfully Treated by Operation. By Dr. A. C. Wilson.

The Treatment of Puerperal Eclampsia by Saline Diuretic Infusions. By Dr. R. Sardine.—The author calls attention to the great value of saline diuretic infusions in the treatment of puerperal eclampsia. In twenty-two cases treated by him in this manner, only three patients died: a death rate of 13.64 per cent. Of the three fatal cases, one patient had a perforating duodenal ulcer; a second, double pneumonia; and the third, marked degeneration of the liver. Of the twenty-two children, thirteen were born dead. The saline solution used consisted of one drachm each of sodium chloride and sodium acetate to the pint of water. From one to three pints were injected under the breast or into the abdominal wall.

British Medical Journal, June 15, 1901.

Hepatic Inadequacy and its Relation to Irregular Gout. By Dr. I. B. Yeo.—By "hepatic inadequacy" the author means such defect or disturbance of the functions of the liver as, while stopping short of causing actual disease of the liver, yet leads to impairment of the general health. He believes that many, if not all, of those cases known as "irregular gout" arise in this way. Uric acid does not cover the whole field of gout; indeed, it spreads widely over other pathological fields that have nothing to do with gout.

The beneficial effects of alkaline sodium solutions in cases of irregular gout are well known; they exert their remedial influence by acting on the gastric, intestinal, and hepatic functions, quite irrespective of any direct solvent action on the sodium biurate.

The symptoms referable to hepatic inadequacy presented by patients with irregular gout are pallor of faces, constipation or diarrhoea, enlargement of the liver, muddiness of the complexion, yellowness of conjunctivæ, and anorexia. The urine is high-colored and of high specific gravity. On boiling and adding nitric acid, various shades of mahogany color are developed. The kidneys are not functionally diseased in these cases, but help in the process of elimination of excrementitious substances which normally pass out with the bile. Apart from individual peculiarities common to the gouty, the safest diet for these patients is the simplest diet. The pounded lean meat and hot-water diet is about the simplest that can be offered to the feeble digestive organs. A limited amount of simple food means digestive ease and freedom from goutiness. There is more in the quality and cooking of the food than in the kind of food. The best wine for patients needing a stimulant is a dry port, long in the wood; the more diuretic it is, the more suitable. The author is opposed to the view that most gouty patients need exercise; his experience has been that it is often difficult to get them to take sufficient rest. In the alkaline sodium salts we have the most valuable and indispensable of hepatic stimulants.

The Chemical Side of Nervous Activity. (*Abstract.*)

By Dr. W. D. Halliburton.—The first and second of the Croonian lectures for 1901. They will be abstracted when completed.

A Report on 620 Cases of Typhoid Fever Treated in the Royal Victoria Hospital, Montreal, during the Seven Years Ended December 31, 1900. By Dr. J. Stewart.—Of the 620 cases of typhoid fever here reported, 34 ended fatally, giving a mortality of 5.4 per cent. In 93 per cent. of the cases the onset was slow, and was characterized by headache and *malaise*. In 7 per cent. the onset resembled that of pleurisy; in 5 or 6 cases, the onset resembled that of a sharp attack of appendicular inflammation. Epistaxis was an early symptom in 12 per cent. of the cases; but it was rarely an initial symptom. In only a very few cases were symptoms of meningitis met with. The percentage of deaths from the various causes was as follows: Perforation, 32 per cent.; intoxication, 29 per cent.; hæmorrhage, 26 per cent.; and miscellaneous causes, 13 per cent.

Out of the 11 cases of perforation an operation was attempted in 8, but in no instance with a successful result. Such operations should be performed within twelve hours after the accident. Little dependence can be placed upon the presence or absence of leucocytosis as diagnostic of perforation. A summary of the work of C. K. Russell upon this subject is given, and his conclusions confirm the author's view. Hæmorrhage occurred

in 34 of the 620 cases (5.4 per cent.), proving fatal 9 cases. In the treatment of this condition the following measures were carried out: quiet, elevation of the foot, the bed, application of cold to the abdomen by means of a Leiter's coil, opium internally, and restriction of diet.

Cholecystitis was met with in 7 cases, one of which proved fatal. A relapse occurred in about 9 per cent. of the cases, the average duration of which was 18 days. In 7 cases the relapse was more severe than the primary attack.

The Widal test was employed in 370 cases, with positive result in all but 8. The earliest date on which the reaction was found was the third day. One case of typhoid without intestinal lesions was met with; typhic bacilli were found in the tissues, and the blood gave a positive Widal reaction.

The routine treatment was hydrotherapy; it was used in about 83 per cent. of the cases throughout the entire course of the disease. The non-bathed cases include (1) rebellious cases; (2) temperature not above 102° F. at any time during the course of the disease; (3) imperfect reaction following the baths; (4) cases admitted late in the course of the disease; and (5) the advent of severe abdominal complications.

The Surgical Treatment of Typhoid Fever. By I. T. J. MacLagan.—Opening the peritoneal cavity in case of perforation of the bowel in typhoid fever is an operation which has been performed often enough, and with sufficient success to give it the standing of a justified and proper procedure. But there is another class of cases in which surgical intervention may be just as beneficial; these are the cases where the sloughs and decomposing discharges are unduly retained in the large bowel producing distention of the colon with temporary paralysis of its muscular walls. The passage of a rectal tube is usually of little avail, and the patient passes into a state of typhoid depression, with distention of the abdomen and failure of the heart. In such cases the author suggests that an opening be made into the large bowel through which it could be washed out. In such cases we have to deal with septic poisoning rather than with typhoid fever; by washing out the bowel as described the septic material would be removed and the distended colon would return to its normal size, but the operation should not be delayed until the patient is *in extremis*. The author has had no opportunity so far to put this suggestion into practice. If left alone such cases surely die while the risk attendant upon the operation suggested would be almost *nil*.

A Case of Typhoid Arthritis Proper. By J. Buchan, M. B.—The author reports a case of typhoid fever occurring in a boy aged eleven years, which was complicated by arthritis of the left elbow joint. The effusion soon suppurated, and the joint was opened and drained. The pus contained only streptococci and staphylococci; no typhoid bacilli. There was nothing to point to rheumatism beyond the pain and swelling of the joint.

On Anæmia in Typhoid Fever. By Dr. T. Houston.—The author has carefully studied the anæmia and leucocytosis of typhoid fever, and reaches the conclusion that the anæmia is not due to destruction of the corpuscles, but to an excessive dilution of the blood plasma. In the same way the diminution in number of the leucocytes is not due to the action of toxins but to the dilution of the blood. The multinuclear elements are apparently diminished, but in reality remain stationary, the same being true of the eosinophiles. The

nuclear elements apparently remain stationary, but in lity are increased. The leucocytes respond to any ammatory stimulus, but, owing to the dilution of the od, their response is apparently slight. The fall of multinuclear elements is roughly proportional to the rease in hæmoglobin, the percentage of which may be en as an index of the dilution of the blood. The tenacy to dilution of the blood in typhoid fever may be to increased activity of the lymphatic system. This ould account for the increase in number of the lympho- es in the blood.

Simple Continued Fever in South Africa. By F. J. Porter, R. A. M. C.

On the Protection from Water-borne Disease Afford- by the Pasteur-Chamberland and Berkefeld Filters. W. H. Horrocks, M. B.—The author's observations ear to justify the following conclusions:

1. Typhoid bacilli are not able to grow through the lls of a Pasteur-Chamberland candle, and if proper e is taken to prevent the bacilli from passing through ws or imperfect fittings, such a filter should give com- te protection against water-borne typhoid fever.

2. Typhoid bacilli can grow through the walls of kefeld candles, the time required being between four l eleven days. When employing this filter, the can- ds should be sterilized in boiling water every third day.

Hæmaturia Following the Administration of Urop- tin. By Dr. W. L. Brown.—The author reports the urrence of hæmaturia in two cases of typhoid fever er urotropin had been given for eight days, and its id subsidence after the drug was stopped. The blad- appeared to be the source of hæmorrhage. Discom- t, which preceded the hæmaturia, should be consid- ed a danger signal when using urotropin. Ten grains the drug was given three times a day.

A Fatal Case of Hæmatoporphyria. By Dr. H. ldo.—The author reports the case of a man, aged rty-three years, who had been in the habit for some rs of taking sulphonal for insomnia. He developed gastritis, followed by delirium and convulsions, and ic paresis; he died on the twenty-fourth day of his ess. The urine was very dark-red in color, and spec- oscopic examination showed bands corresponding to se produced by hæmatoporphyria.

Hibernation of Anopheles in England. By Dr. G. F. Nuttall.—The author reviews the various observa- tions that have been made as to the hibernation of the eral species of anopheles in England. He himself has erved the larvæ of *Anopheles bifurcatus* to hibernate. he larvæ of *Anopheles maculipennis*, which were in the same tank, invariably died as the winter progressed.

On a Common Source of Diphtherial Infection, and eans of Dealing with it. By Dr. R. T. Hewlett and H. M. Murray.—In this communication the authors lw the frequency with which children whose throats o presumably healthy may serve as sources of diph- thia. The Klebs-Loeffler bacillus and pseudo-diphthe- bacillus exist in the throat in many children without lucing symptoms. Of 385 children examined by the uors, only 235 were free from both kinds of bacteria. he Klebs-Loeffler bacillus was present in fifteen per ct. of the cases.

Mouth cleaning in infants, and teeth cleaning in ng children, should be vigorously insisted upon, and ng should be discouraged.

Klinisch-therapeutische Wochenschrift, May 26, 1901.

Medical Treatment of Perityphlitis. By Professor Bourget.

Treatment of Anorexia by Cryotherapy.—Dr. Izso Hönig records remarkable results from the use of "carbonic-acid snow," *i. e.*, carbonic acid at a tempera- ture of 65° below zero (C.). For the anorexia of acute infectious diseases or of the chronic ailments, the local application of this snow is said to restore the appetite almost immediately.

Münchener medicinische Wochenschrift, May 21, 1901.

Technics of Amputation of the Vermiform Ap- pendix.—Dr. Otto Lanz recommends squeezing of the site of amputation of the appendix before its incision by the angeiotribe. By this means the muscular and mucous coats are sharply retracted and the serous cover- ing alone requires ligation. He regards this method as infinitely superior to inversion of the stump and says that it is the safest means of amputating the appendix.

Cholecystogastrostomy.—Dr. F. Krumm reports two successful cases and considers it a very desirable opera- tion in cases in which a fistula cannot be established be- tween the gall-bladder and the duodenum.

The Prophylaxis of Venereal Diseases.—Professor Thomas von Marschalko, who was a member of the Brussels conference, urges the instruction of the laity in methods of self-protection. Men should be taught that an intact skin, before and during intercourse, is the safest measure against contracting syphilis. He feels very doubtful as to the effects of State regulation upon the spread of venereal disease, and he is very certain that it cannot be improved upon. He does not believe that prostitution can be abolished.

Inhalation of Rarefied Fluids.—Dr. M. Sænger says that we must accept as proved the inhalation of rarefied fluids within the larynx and in the respiratory passages below it. The inspiratory effort no doubt carries the fluid into the deepest parts of the lungs. He thinks, however, that the amounts inhaled are so minute that their therapeutic value is almost worthless.

Different Forms of Degeneration. By Dr. Adler.

Case of Precipitate Labor. By Dr. H. Witthauer.

Portable Aseptic Hypodermic Case. By Dr. Salm.

Acute Yellow Atrophy of the Liver. By Dr. Aby Bey Ibrahim. (*Concluded.*)

May 28, 1901.

Vaporization of the Uterus.—Dr. H. Fuchs advises the use of narcosis for atmocausis of the uterus to avoid the pain of cervical dilatation as well as to enable a thor- ough pelvic examination to be simultaneously made. In twenty-two cases the results of vaporization were far more satisfactory than curetting for combating profuse menstruation at the menopause, with which alone his paper deals.

Vaporization of the Uterus. By Dr. S. Lachmann. (*Continued article.*)

Injurious Results of Amputation of the Cervix.—Dr. M. Grafe protests against amputation of the vaginal

portion whenever there is an erosion of that portion of the cervix. When erosions do not heal under prolonged treatment, however, they had better be carefully watched for fear of malignant degeneration. The operation performed upon nervous and hysterical women is likely only to increase their infirmities.

Causes and Treatment of Dysmenorrhœa.—Dr. A. Theilhaber says that a real stenosis of the cervix rarely accompanies even a severe ante flexion. Stenosis usually arises from medical treatment by caustics. Moreover, stenosis has nothing to do with the ætiology of dysmenorrhœa. He does not regard metritis or endometritis as causes of painful menstruation, if they are not complicated by some peritoneal involvement. Oöphoritis alone cannot evoke dysmenorrhœa unless there is a co-existing perimetritis. He speaks encouragingly of Fliess's work in cocaineizing the so-called "genital spots" in the nose, and thinks it due to a vasomotor paralysis leading to anæmia of the uterus. (*To be continued.*)

Prolapse of the Urethra in the Female.—Professor Glævecke says that acute prolapse of the urethra must be treated by reposition and by the application of some apparatus to keep it in place until it remains so spontaneously. Caustics and astringents should also be applied to the urethral mucous membrane. Chronic cases are to be treated like cases of rectal prolapse, by radial incisions with the actual cautery.

Instrumental Perforation of the Uterus. By Dr. F. Schenk.

Agnathia.—Dr. Kuse reports five cases of congenital absence of one or both jaws, with special reference to the defects of the tongue. In two cases the hyoid ring was also absent, with a sacular dilatation of the pharynx. In all the cases with a well-developed hyoid ring the indications of a tongue were present, the posterior portion of the tongue being plainly in evidence, the anterior part, however, absolutely wanting. The thyroid gland can develop well, despite a high degree of malformation of the pharynx or the hyoid ring.

Presse médicale, May 22, 1901.

Hæmoglobinuric Bilious Fever in Paludism.—M. Troussaint concludes that such a condition has been actually proved to exist in the tropics, and can be shown to be due to hepatic changes in malarial fever, acting upon the blood by some form of demineralization. Its treatment consists in the administration of salts of quinine in small doses, but sufficiently large to destroy the hæmatozoa. Intravenous injections of sodium chloride are also necessary to restore the blood to its normal condition by increasing its isotonic power and by eliminating from the blood the sugar, the uræa, and the bile, which are the deleterious agents.

Radical Cure of Cervicitis.—M. Petit describes Poney's method of excising a conical piece of the cervix with its mucosa, and uniting the raw surfaces with a purse-string suture.

Gazette hebdomadaire de médecine et de chirurgie, May 19, 23, and 26, 1901.

Lead Colic.—M. Bernard gives a lengthy clinical study containing a mass of detail, which should be read by those interested.

Intestinal Obstruction Due to Vicious Position of the Intestines.—M. Frœlich reports two such cases, one due to a torsion of the entire mesentery about its pedicle the other to rotation of the cæcum about its own vertical axis. In these cases there was absence of fecal vomiting, few signs of obstruction, the occlusion not being absolute, and there was considerable ascites.

Rocking of the Scapula in the Reduction of Subcoracoid Dislocations.—M. Berthaut says that by careful and slow manipulation of subcoracoid dislocations of the shoulders, the reduction becomes easier than usual, if the scapula can be made to move or rock upon its long axis simultaneously with the other approved manœuvres.

Riforma medica, May 9, 1901.

Drug Rash after the Use of Phenocoll Hydrochloride. By Dr. Giuseppe Cao.—The author has observed an interesting case in which the use of phenocoll hydrochloride in a man aged twenty-eight years gave rise to an eruption. He had been suffering from an attack of malarial disease, which proved resistant to quinine, even after subcutaneous injections. One gramme of phenocoll hydrochloride was given in two doses, and, to the author's surprise, an eruption appeared on the neck, the flanks, and the arms, consisting of bright-red macules of the size of a hempseed, discrete, with clean-cut margin, disappearing on pressure. There was slight pruritus and the malarial paroxysm recurred at the usual hour without change. The eruption disappeared soon after this paroxysm, but on the next day it reappeared three or four hours after the administration of a gramme of phenocoll. The same series of events followed on the third and fourth day. Two grammes of the drug produced a more intense eruption, which lasted longer. The patient was finally cured by change of climate and a stimulating treatment. The drug must therefore be added to the list of drugs that may produce eruptions.

"Lavage of the Organism" in Experimental Tetanic Infection. By Dr. C. Tonzig.—"Lavage of the organism" consists in the introduction into the circulation of an indifferent fluid such as normal salt solution, in large quantities, in order to "wash out" the toxins produced by pathogenic germs. This method of treatment presents attractive possibilities in tetanus, which is an essentially toxic disease. Sanquirio, in 1888, proposed the use of this method in alkaloidal poisoning, *e. g.*, with strychnine. In this way he saved dogs from alkaloidal poisoning by causing the poison to be eliminated in the excretions, the volume of which was increased by the injection of salt solution. Since then Gomez has successfully used this method in a child with tetany from influenza; Lasletta, in grave cases of diphtheria, with threatening heart failure; Bose and Baylae, in typhoid fever; and Coilland, in tetanus. The author performed a series of experiments on tetanized animals some months before the publication of Coilland's case, and now publishes his results. He concludes that: (1) Lavage of the organism through the peritoneal cavity in tetanus cannot be said to give absolutely certain curative results; (2) this fact helps to prove that the virus of tetanus does not circulate in the blood, but is fixed in the tissues; (3) when the penetration of the toxin into the organism is not very rapid, lavage with artificial serum retards the appearance of tetanic symptoms and delays death for

few days. Hence this method of treatment should not be rejected entirely and may serve as an adjuvant to serumtherapy, especially when the serum cannot be obtained at once.

On the Toxicity of Strychnine when Injected into the Body, with Special Methods and Procedures. By Dr. Leopoldo Baruchello.—Czyhlarz and Donath (*Centralblatt für innere Medicin*, April 13, 1900) have shown that if an extremity of a guinea-pig is ligated and a fatal dose of strychnine is then injected at the peripheral part of the limb, the guinea-pig will not die, even though the ligature is removed in four hours. They conclude that the muscles, lymph, and blood of the guinea-pig produce a substance which is capable of neutralizing strychnine. The author has performed a series of experiments on animals and has studied the various questions which arise in this connection. He concludes that the special resistance to strychnine which, under certain conditions, may be created in guinea-pigs, depends principally on the slowness of absorption which is secured by the method of injection and on the antitoxic properties of the tissues. The delay in the absorption of the poison is very important, for it renders possible the development of the complex antitoxic action of the tissues.

Formation of Calculi around a Catheter which had for a Long Time Remained Forgotten in the Bladder. Unsuccessful Attempt at Suprapubic Cystotomy. Extraction after Peritoneal Vesical Incision. By Dr. L. Rizzo.—A case, the features of which are given in the title. The patient was a man, twenty-eight years of age. The calculus was discovered by means of a sound; the catheter had remained in the bladder for several years.

May 14, 15, and 16, 1901.

Notes on Gastric Semeiology. By Dr. Guglielmo Memmi.—A series of short articles on the diagnosis of gastric affections. The author considers two questions: (1) The chemism of the stomach with the various test meals; (2) sarcinae and the bacillus of Oppler-Boas in cancer of the stomach.

He has studied the results of administration of the various test meals, *i. e.*: (a) The test meal of Ewald and Boas (100 grammes of bread and 100 grammes of water); (b) the test meal of Andrea Ferrannini (100 grammes of lean meat and 150 grammes of water); (c) the test meal of Sée, a modification of the breakfast of Lenbe-Riegel (100 grammes of bread, 100 grammes of lean chopped meat, and 150 grammes of water); (d) the test meal of Talma-Troller (200 grammes of broth, made with Liebig's beef extract. He concludes as follows as regards these test meals: 1. With the meals of Talma-Troller and Ewald-Boas, phanerochlorhydria is almost constant, while with those of Sée and Ferrannini, particularly with the latter, cryptochlorhydria predominates. 2. With Talma-Troller's meal a gastric juice is obtained which gives the smallest total hydrochloric acidity; with that of Ewald-Boas, one that gives a medium total hydrochloric acidity; with the other meals, one that gives the maximum total hydrochloric acidity. 3. In order to get a true estimate of the conditions in a stomach, one must try the various test meals and form a judgment according to the results obtained.

The author's researches on cancer of the stomach are summed up in the following conclusions: 1. *Sarcina ventriculi* may be found with considerable quantities of lactic acid and absence of hydrochloric acid in cases of cancer of the stomach. 2. The coexistence of the sarcina and the filiform bacillus is not infrequent. 3. The bacillus of Oppler-Boas cannot be regarded as a pathognomonic sign of gastric cancer.

Vratch, April 28th (May 10th, new style.)

Changes in the Blood in Animals with Intestinal Self-intoxication. By Dr. A. J. Krasnoff.—The number of red cells is diminished by from 15.6 per cent. to 72.5 per cent. The number of white cells is sometimes increased, sometimes diminished. The maximum decrease was 80 per cent., the maximum increase 60 per cent.; the minimum increase was 10 per cent., and the minimum decrease was 10 per cent. The quantity of hæmoglobin was considerably decreased. The specific gravity falls, but this fall is not always proportionate to the number of red cells. The quantity of iron is diminished.

On Sporadic Elephantiasis. By Dr. L. V. Orloff.—(Concluded).

Haffkine's Lymph and other Remedies that Produce Active Immunity against the Plague. By Dr. A. F. Vigur.—In speaking of the action of Haffkine's serum upon man, the author states that the results of numerous experiments in India have shown that this serum produces immunity in the majority of persons inoculated. This statement is based upon the results reported by a number of authors. The first attempt at inoculation of human beings with "killed" agar cultures of the plague bacillus was made by Kolle in 1897. Lustig and Galeotti, in Florence, also experimented on men with plague cultures. In view of the small number of inoculations with Lustig and Galeotti's serum, it is impossible to give statistics which would show the efficiency of the treatment and the duration of the immunity with this substance. Injections of the Italian serum in doses of from two to three milligrammes are probably followed with less fever than the injection of the other serums. After the injection of Haffkine's serum in the ordinary dose for immunization there is a rise of temperature, usually to 102° F., sometimes to 104° F., and rarely to 105° F. The fever remains for from fifteen to forty-eight hours, sometimes longer, and at the site of the injection there is considerable pain, swelling, and redness on the following day. The local symptoms remain for from three to five days, and then disappear. (To be concluded).

Kumyss Treatment and some Kumyss Settlements in Ufa. By Dr. P. V. Zesarievsky.—(Concluded).

Journal Akouscherstra y Gienskich Boliesney, February, 1901.

The Bacteriology of the Uterine Cavity and of the Falloppian Tubes in Non-pregnant Women. By Dr. P. V. Michine.—The author gives statistical data concerning the various germs that have been found in the uterus and Falloppian tubes of non-pregnant women. He concludes that the significance of germs in the causation of inflammations of the internal genitals in women has not yet been settled, except as regards the *Micrococcus gonorrhææ* and the *Bacillus tuberculosis*. In order to study this question further, he examined the internal genital organs in a number of cases, and made forty-nine observations, including twenty-four uteruses. Of these, eight showed glandular endometritis, ten interstitial endome-

tritis, four mixed forms, and two hæmorrhagic. In one case of diffuse endometritis there were streptococci, and in two cases the Fallopian tubes contained streptococci, and in both these germs were found in one tube only. *Staphylococcus pyogenes aureus* was found in one uterus, and in two cases in the Fallopian tubes; in one case, in one tube only, in the other, in both tubes. *Micrococcus flavus liquefaciens* (Fluegge) was found once in the uterus in diffuse endometritis. A diplococcus resembling closely that described by Tchaikovsky was found in one case in a uterus showing diffuse endometritis. *Micrococcus tetragenus* (Koch-Gaffky) occurred three times in tubes, in each case in one tube only. In one tube there was a diplococcus, the nature of which could not be well determined. The gonococcus occurred in one case in diffuse endometritis in the uterine cavity. The uterus could not be examined in all the cases, as a solution of iodine was always injected into the cavity before hysterectomy. The cultures were always obtained pure, and there was no symbiosis. The virulence of the germs was only tested in two cases. In the Fallopian tubes the germs were found in the presence of old catarrhal changes, and also in some cases with healthy mucous membrane, so that nothing can be said as to their significance. The author has also studied the microscopical features of these specimens. In a subsequent article he will study the anaerobic bacteria found in the uterus and appendages under various conditions.

Fifty-three New Cases of Inflammatory Conditions of the Uterine Appendages Treated with Electricity. By Dr. I. S. Kalabine.

The Treatment of Diseases of Women in Franzensbad. By Dr. L. Th. Nenadovitch.—The author has investigated the methods of treatment employed in Franzensbad for diseases of the female generative organs, especially the course of "moor" or mineral mud baths. He concludes that (a) the existing data as to the physiologic effects of mud baths are not sufficient to place this method of treatment on a scientific basis; (b) all methods of therapy with mud baths can be classified into two categories—baths with heat and sweating, and baths that do not raise the temperature of the body or cause increased perspiration; (c) when compared with the laws of absorption of blood and lymph it is evident that both methods act in the same way, namely, according to the principle of wave-like action on the organism, the conservation of energy, and the balance of chemical affinity; (d) the sweating method is more effective than the other, both in theory and in practice; (e) Franzensbad belongs to the class of watering places where the non-diaphoretic method is used; (f) in the treatment of diseases of women there, the ferrous waters that the patient drinks have a great deal to do with the result; (g) the combination of mineral-water drinking and mud baths, as used in Franzensbad, is practically equivalent to the diaphoretic method of treatment, as is proved in practice; (h) the non-diaphoretic method is perfectly harmless, while the diaphoretic method is accompanied with a certain amount of risk; (i) the waters of Franzensbad may be prescribed in various conditions of the digestive tract. The climate there is adapted to the treatment, and the management of the place is satisfactory.

On the Treatment of Postpartum Parametritis with Weight Pressure. By Dr. S. A. Gliadkoff.—The author reports his experience with this method, which was first suggested by Schauta. The patient is placed on her back, with elevated pelvis, a colpeurynter is introduced

into the vagina, and the bag is filled with mercury. A bag of shot is placed on the lower part of the abdomen. This pressure is said to cause absorption of exudates, etc. Later, massage, with or without baths, is used to remove infiltrations. In three cases, the histories of which he cites, the author seems to have attained satisfactory results with this plan.

An Attempt to Apply the Laws of Evolution to the Study of the Causes of Determination of Sex (concluded). By Dr. N. Schipoff.—The author has studied 368 pregnancies in order to discover the nature and laws of sex determination. He studies the question from a number of points of view, giving statistics for each factor which may play a rôle in the determination of sex. He distinguishes "two types of pregnancy," one for boys and one for girls. The pregnancy leading to the birth of a boy, according to his statistics and a comparative study of other writers, is characterized as follows: The parents are comparatively poor, physically healthy, sober, and do not use tobacco, the father is somewhat older than the mother, the wife is over nineteen years of age, the husband over twenty-four. The wife is a brunette and has certain masculine characteristics in her mental sphere. She is comparatively tall, menstruation has begun comparatively late, and her psychic nature exhibits marked energy and passion. Both parents love each other passionately. Conception has taken place in a sober state on the part of both parents, and on a day which approached the full moon (?). During the first months the wife suffers from nausea, vomiting, and retching, and she grows fastidious about her food, preferring strongly flavored articles of diet. She eats little and grows thin. She gets spots on her face. Mentally she is cheerful, of equable temper, has little desire for sleep, and shows a tendency to work and exercise. The sexual function is not markedly changed. She sleeps on the right side and feels the first movements of quickening on the left. The labor is comparatively short, and milk usually appears on the third day.

In a typical pregnancy "with a girl," the parents present exactly the opposite conditions from those stated in the foregoing paragraph, *e. g.*, they are comparatively wealthy, weak, inclined to alcoholic drink and to tobacco (in Russia tobacco is used frequently by women of the higher classes), and they are often under age. The wife is frequently a blonde, is intensely womanly in her character, etc., etc. The author has found that "typical" pregnancies are more often found when the child is a girl, while mixed, or atypical ones, are more frequently met with when the child is a boy. Thus he thinks that a change in a single factor is sufficient to "turn the scale," so to speak, in favor of a boy. The development of sex in the embryo does not depend upon a contest between the male and female elements, but upon the mutual capacity of the parents of developing a greater or lesser energy and vital activity. All properties and peculiarities of the human soul are common to both sexes, but the forces of atavism and heredity act more markedly on the female. Variation is more common to the male. The Schenck theory is not founded on facts, as a meat diet produces girls, and not boys. The study of popular notions regarding this question will give a better guide for prognosis of sex than all modern theories (?). The author places in the first rank of factors influencing sex the psychical qualities of the parent, in the second rank their physical qualities. He sums up by saying that "a boy must be earned by the personal efforts of the parents, while a girl is given to them gratis."

Proceedings of Societies.

AMERICAN MEDICAL ASSOCIATION.

Fifty-second Annual Meeting, Held in St. Paul on Tuesday, Wednesday, Thursday, and Friday, June 4, 5, 6, and 7, 1901.

Section on Laryngology and Otology.

(Concluded from page 1009.)

The Relation of the Middle Turbinate Body to Chronic Nasal Diseases. By Dr. C. S. Baker, of Bay City, Mich.—The author said that the nasal chambers could be considered as mere ducts, and we must regard them as avenues for cleansing the upper air passages. By nasal operations we drained the upper cavities by removing the obstructions. The ethmoidal cells pressed against the septum; by opening the cells we obviated the necessity for a second operation.

Dr. W. E. Casselberry, of Chicago, said that we should not interfere with the middle turbinate unless it was diseased or obstructed drainage. In most cases of empyema, drainage by operation alone could not be relied on. The operation was not devoid of danger; there was liability to severe hæmorrhage or infection. After the use of suprarenal capsule or cocaine the tissues became shrunken and parchment-like, and often their incision was followed by violent and persistent hæmorrhage. Adrenaline, however, was of great assistance, its one drawback being its liability to cause secondary hæmorrhage.

Packing with iodoform gauze for twenty-four hours could be resorted to after removal of the middle turbinate. The speaker said he considered it unsafe to send a patient home without this provision.

Dr. Warden considered the middle turbinate the chief seat of trouble in the nose. The antrum could be drained by removal of this bone. A deviation of the septum was of minor importance. He thought the initial lesion of catarrhal disease could be traced to the conditions of the middle turbinate.

Dr. Cobb, of Lynn, considered drainage of paramount importance. He said that there was no difference between chronic discharges from the nose and those from other parts of the body. By removal of the middle turbinate we secured efficient drainage.

Dr. E. Fletcher Ingals, of Chicago, said that the operation under discussion relieved the cerebral and mental symptoms, as well as the pressure and obstruction incident to chronic nasal disease. He objected to the use of gauze, as it insinuated itself into small cavities and could not be easily removed. He found the use of cotton preferable.

Dr. Redmond W. Payne, of California, also favored the use of cotton. He believed that the repeated use of adrenaline would prevent hæmorrhage. It could be continued for several days. He also advised the removal of the middle turbinate beneath the mucous membrane; by this method there was less bleeding and the incision was easily sealed.

Dr. E. Mayer, of New York, spoke of the danger of permitting patients to go home without packing the nose after removal of the turbinate body. In some cases, instead of employing packing, he used the adrenaline every two or three hours, and found the effect satisfactory. He recalled the treatment resorted to previously to the days of hæmostatics: The patient, after operation, was put to bed and kept there for three or four days;

no packing was used and the result was even more successful than by the present method.

Dr. Baker, in closing, said that, from his experience, gauze did not insinuate itself into the smaller cavities any more than cotton did. He did not think it was always possible to put the patient to bed. He had been obliged to resort to packing in many cases, but considered it dangerous, as pus might thus be retained and produce infection.

Asthma as a Result of Nasal Conditions. By Dr. J. H. Farrell, of Chicago.—Dr. Farrell said that all nasal affections had a tendency to produce asthma. As regarded treatment, abnormal nasal conditions should be corrected, preferably by cutting, and cardiac and rheumatic conditions should receive attention. The reader cited three cases of asthma which were relieved by operation on the nose. He expressed the belief that the majority of cases of asthma were due to abnormal nasal conditions.

The Effect which the so-called "Catarrhal" Diseases of the Nose and Throat may have upon the General Health. By Dr. C. M. Cobb.—The reader said that by relieving the local catarrhal conditions the general health would improve.

Dr. Casselberry thought the local conditions would improve if the general health was good and was relieved of dyscrasia.

Empyema of the Frontal Sinus. By Dr. E. Fletcher Ingals, of Chicago.—The author regarded this as a rare condition. The prominent symptoms were pain and swelling in the region of the affected sinus, and nasal discharge. When pus was present, there was an elevation of temperature.

In some of these cases he found bony defects; in others the mucous membrane was swollen, closing the outlet of the sinus. The defects were sometimes congenital. Septic meningitis followed caries of the bones with possible rupture into the cranial cavity. This condition, the speaker said, was not found in patients under seven years, as the sinuses did not develop before that age. Chronic cases were the result of polypi and other nasal obstructions. The pain usually extended to the eye and photophobia was a prominent symptom. The pain might extend along the supra-orbital nerve. Relief was afforded by the discharge of pus. In some cases the diseased area might be outlined by transillumination, but as a diagnostic point this was of little value, unusual density of the walls of the sinus or absence of the sinus interfered with the value of the test, and in rare cases the light failed to reveal the presence of pus.

Anomalies of the Frontal Sinus and their Bearing on Chronic Sinusitis was the title of a paper by Dr. Redmond W. Payne, of California. The author cited several cases of anomalies that had come under his observation, together with the difficulties encountered in finding the source of the pus.

Dr. Casselberry referred to three cases in which there was no opening between the two sinuses, and in one case there was no septum. In two cases there was a direct passage to the maxillary canal.

Carcinoma of the Nasopharynx.—Dr. Chevalier Jackson, of Pittsburgh, cited thirteen cases of this rare disease, which was found in about equal proportion in males and females. In fifty per cent. of the cases, the patients were over forty years of age. The disease was not specially localized, and had a tendency to extend downward. Pain, fœtor, and hæmorrhage were the early symptoms. He favored early and complete ex-

tirpation as the best means of relief. Unfortunately, most cases were operated on too late. Death usually occurred within a year, even after total extirpation. The palliative treatment added to the comfort of the patient. The growth could be snared and the surface dusted with aristol. Extirpation of the glands afforded some relief.

Sarcoma of the Nasal Passages, with Report of Case.—Dr. Dunbar Roy, of Atlanta, Ga., stated that sarcoma of the nasal passages was on the increase, and is encountered with greater frequency in the region of the turbinated bodies. It was not as malignant here, however, as in other localities. He attributed the disease to a disturbance of embryonic tissue, and spoke of one case where disease was apparently carried by instruments. The prominent symptoms were closure of the nasal cavity and gradually increasing difficulty in breathing.

Dr. John N. Mackenzie, of Baltimore, objected to small parts of a suspicious growth being removed for microscopical examination. This subjected the patient to the risk of infection, caused profuse hæmorrhage and stimulated the growth. This was more especially true in growths of the larynx. The removal of a piece usually means the beginning of the end.

The Diagnosis and Treatment of Mastoiditis. By Dr. E. B. Dench, of New York.—No delay should be countenanced in dealing with mastoiditis. Opening the mastoid cells, under proper antiseptic precautions, is not a dangerous operation. Every cell should be scraped and the sharp scoop should be used until the firm bone is touched. When the symptoms are not prominent, an exploratory incision is justifiable. Paracentesis does not give the necessary results, as the cells are not properly drained by this measure. Washing out of the cavity is essential.

Dr. Sherman, of Cleveland, considered it unnecessary to operate in many cases. He regarded the operation as a dangerous procedure, causing severe hæmorrhage and even death. He called attention to the intimate relationship between the circulation of the mastoid and that of the meninges. He regarded paracentesis as safer and equally effective.

Dr. Cobb said that if pus was present artificial means of escape must be resorted to. When the drainage was good there was no necessity of opening the mastoid cells.

Dr. French, of Illinois, said that cases with severe pain or with pus escaping from the meatus required an operation. Operation was usually delayed too long, and meningitis resulted. He did not consider it a dangerous operation.

Dr. Baker said that there was usually more delay in resorting to operation in mastoiditis than to any other surgical operation. By not operating, the surgeon neglected his duty.

Mastoiditis after Subsidence and without Recurrence of Tympanic Disease.—Dr. Hiram Woods, Jr., of Baltimore, related a case in which mastoiditis occurred twelve days after the disappearance of inflammatory symptoms. Pus was found in the mastoid cells. He did not believe cold would abort mastoiditis. It masked the symptoms and increased the danger of hæmorrhage. A sufficient degree of cold could not be maintained to kill all the germ formation.

Dr. Dench favored the use of cold, having seen cases aborted by it.

Dr. Hollander desired to call the attention of the members to the good results of allowing the wound to fill up with blood clot and sewing up the wound after operation.

Section in Diseases of Children.

(Continued from page 1063.)

Prolonged Intubation. By Dr. Edwin Rosenthal.—With the advent of diphtheria antitoxine the operation of intubation obtained a fixed position. Before that time it was an expectant procedure and in a great measure experimental. To the antitoxine are also due the very many accurate results obtained in the study of the progress, as well as of the sequelæ, of diphtheria, especially those of the laryngeal type and those most serious cases requiring intubation. By this procedure we are not only able to relieve the impending suffocation, but we can cure the patient. Where before we were expectant, now we are more certain. The author goes into the various difficulties, taken up by different authors, in intubating and extubating, but sums up his general rule of practice as follows: "The tube should be removed within five days, unless it is removed by expectoration before, and should then be no longer required. If the patient requires the tube longer than this time it will be impossible to state when it will no longer be required. Cases in which the tube must be replaced, even after a week, should be considered abnormal, and should be classed under the head of prolonged intubations. Welch reports a case in which the patient required the tube for eleven months, finally dying of suffocation. Engelmann and others report the same results."

A case in a patient aged two years and seven months is reported. After the primary evidence (faucial diphtheria) had disappeared under the administration of antitoxine, a reinfection of the laryngeal type occurred on the seventh day. Intubation was performed, and a fortieth of a grain of strychnine given. The tube was taken out on the fifth day, but after thirty-six hours had to be replaced on account of stenosis. The tube was worn, being removed occasionally, for a period of thirty-six days. The tube is to be removed every two or three days, using progressively smaller tubes till the child no longer requires a tube.

Discussion.—Dr. Shurly referred to 240 cases of diphtheria, with a mortality of sixty. Of this number, eight were intubated. Prolonged intubation might be considered as those cases in which the tube remained in position more than six days, whereas ordinarily it should be removed on the fourth day. In these cases 3,000 units of antitoxine were always given immediately. Of the eight cases intubated, all recovered except one. The causes of bad results were usually traumatism or cicatricial bands. Plated tubes should be dispensed with.

Dr. Golden used the suprarenal glands wherever there was œdema. A small piece of silk thread was always attached to the tube so as to enable it to be easily withdrawn. It was often not necessary to withdraw the tube because the child would cough it up or pull it out.

Dr. I. A. Abt thought that the sooner the tube could be taken out the better it was for the child. It should be removed every morning; to allow it to remain in continuously caused œdema, trauma, etc. His custom was to remove it in twenty-four hours if possible. There were cases in which a tube could not be introduced into the larynx. This might sometimes be due to the fact that all of the tubes sold at the shops were not properly made.

The Prevention of Pulmonary Tuberculosis in Predisposed Children. By Dr. John A. Robison.—Before the discovery of the bacillus, hereditary tuberculosis was supposed to be of great importance, but in the light of

modern scientific inquiry infection has supplanted heredity. Direct transmission is extremely rare. Cases of tuberculosis occurring during childhood are in nearly all cases due to direct infection, so many statisticians claim, though an equal consideration of the two factors, heredity and the bacillus, must, I think, be maintained. Healthy individuals possess certain degrees of immunity to tuberculosis as well as other infectious diseases, and this immunity is transmitted to the offspring. If one parent is tuberculous the immunity is weakened. If both parents are tuberculous, the immunity is lessened to a greater degree, and there is engrafted on the progeny a cellular nutritional weakness. Children of tuberculous parents are easily affected, both directly and indirectly. Preventive treatment should commence with the ancestors. The education of the people would mean the improvement of the coming generations. A child should never be suckled by a tuberculous mother; as the babe grows, the diet should contain more fat. Early, a taste for hydrocarbons should be cultivated. Pure candy in moderation is beneficial to growing children if given after, not between meals. Children do not drink enough water, which is a great aid to nutrition and acts as a solvent for the effete material in the body. The diet should contain plenty of nitrogenous food. The period of puberty is a critical one. Enforced ignorance of the sexual laws oftentimes allows youth to fall into vices which weaken the cellular and organic structure of their bodies. The youth should be educated in such necessary physiological laws as tend to preserve the integrity of all the tissues and maintain nutrition at its highest point. Better hygiene should be secured in our schools. Those youths with a tendency toward tuberculosis should choose vocations that necessitate their being out of doors a large part of the time. The question of clothing is a most important one, especially if the patient is a girl. The patient should be warmly and loosely clad. A child with a predisposition toward tuberculosis should not wear a corset, which cannot help interfering with the processes of nutrition and development of the respiratory functions of the lungs. Thin shoes, insufficient head covering, or deficient underclothing are the stepping stones to tuberculosis. Cleanliness is a great preventer of germ infection. Hydrotherapy is of great value. Perfect hygienic surroundings, with a maximum of fresh air and sunshine, are prerequisites. Parents should be warned as to the danger of neglecting such diseases as measles, whooping-cough, influenza, amygdalitis, adenoids, etc. The feeble-minded are especially liable to a tuberculous disease.

Discussion.—Dr. Wood thought that there was a great necessity for the stricter enforcement of laws regarding the marriage of tuberculous people.

Dr. Work referred to the supreme importance of proper clothing. People should change their clothing as the weather changed. The two great objects of clothing were equal warmth and equal pressure.

Dr. Slagle pointed out that tuberculosis began in the stomach, through the influence of impaired nutrition, with consequent weakening of the power of resistance.

Protracted Influenzal Pneumonia in Infancy. By Dr. Frank X. Walls.—It has been observed that infants are in a high degree immune to influenza. Influenza, however, in infants frequently runs into protracted pneumonia. Nursing children are almost absolutely immune, even though their mothers are seriously stricken with the grippe. This immunity is explained by assuming that a potent antitoxine is eliminated in the maternal milk.

Infants artificially fed are more susceptible to this disease as well as to others. Comby reports a case of grippe in an infant only seventeen days old. Relapses among children are not rare. The symptoms often come on very much like severe gastro-intestinal infections. Later, involvement of the respiratory tract occurs. Cough is at first short, but later increases in intensity until it is paroxysmal and continuous, similar to that of pertussis. Breathing is rapid, hurried, and jerky. More or less coryza is present in most of the cases. Oftentimes, inflammation of the middle ear, rupture of the drum, and discharge of mucopus complicate matters. The sputum was examined in all cases and the influenza bacilli were demonstrated. The pneumonia was clinically lobar. The consolidation was slow in development, with diffuse bronchitis over the remainder of the lung. The nervous system was signally exempt in the cases coming under the author's notice. The occurrence of an exanthem closely simulating the scarlatina rash, which has been pointed out by many authors, was wanting in the cases under consideration. Diagnosis is sometimes difficult, and the disease may easily be confounded with gastro-intestinal infections, ordinary bronchopneumonia, malaria, sepsis, or miliary tuberculosis. There is no specific treatment for influenza, but the little patient should be kept quiet and be fed on a nutritious diet suited to the digestive capabilities of the infant. Nauseating cough mixtures should be avoided. In the event of cardiac or respiratory failure, stimulation should be given as indicated. Cold applications to the skin frequently act in a happy manner in cases of threatened suffocation.

Congenital Malformations. By Dr. Carl Beck.—The author presented a very interesting paper on this subject and showed numerous Röntgen-ray photographs to demonstrate the cases reported. The most frequent abnormality of the upper extremity, he said, was polydactylism. Congenital deficiencies were naturally hard of correction, but even in such cases surgery was not without resources. Eiselsberg had successfully transplanted, for instance, a toe to the hand. The Röntgen rays were manifestly of great value in determining just what were the conditions present.

Membranous Colitis. By Dr. Charles Douglas.—Membranous colitis occurs most frequently in infants over six months old and less than two years. The stools resemble those of catarrhal enteritis, except in the amount of blood. The only feature which establishes a diagnosis is the occurrence of the pseudo-membrane. The severity of the attack and the gravity of the prognosis are in proportion to the amount of mucus passed daily and the length of time it continues. If for longer than ten days, the prospect of recovery is not good. It is rarely seen in nursing infants. A microscopic examination of the membrane shows that it is structureless and like a mass of fibrin, with no mucus or epithelial cells.

The cases presented show that different bacilli have the power, by their irritative qualities and the result of their toxines, to form this false membrane on the mucous membrane of the bowels. It is important to recognize that the character of the food is the principal ætiologic factor in the beginning of this trouble.

A Case of Ureteral Calculus. By Dr. W. W. Keen.—In this case the calculus was accurately located by the x rays before the operation was performed. The patient gave the usual history of stone in the ureter and, since a recent attack of scarlet fever, the paroxysms of pain in the left side have been more frequent and severe.

The patient was ten years old. On admission the left side of the abdomen was so painful that a diagnosis was impossible as to location of the stone, though the diagnosis of calculus, which had already been made by his physician, was perfectly clear. The photograph shows a calculus about one half the size of the last joint of the little finger. In the left ureter, a little below the level of the pelvic brim near the bladder, there was considerable difficulty in finding the ureter at the operation, as it was imbedded in a hard mass in which the ureter was apparently lost. On an examination the stone was found to be dark in color with a reaction for mucin; the shell was of calcium phosphate with a trace of organic matter. On the opening of the ureter about one quarter of an ounce of urine escaped from the somewhat hydronephrotic kidney. The ureter was packed with iodoform gauze, which was removed on the second day, and recovery was uneventful.

Dr. Keen also referred to four cases in which he had skiagraphed forty-seven cases of stone in the ureter. In most of these cases the stone had been subsequently passed, so that it was advisable to wait in most cases unless the stone was large, rather than resort to surgery, since the surgical operation was difficult, and in nearly all cases where the calculus was small it usually passed off itself.

Dr. Clifton Scott agreed to the extraordinary value of the x ray in these cases, but thought its value was negative as well as positive. He had operated on a case diagnosed as calculus from the clinical symptoms. The diagnosis seemed perfectly clear, but at the operation it was found to be an endothelial growth and no calculus at all.

Dr. Keen also referred to four cases on which he had operated for stone and the stone had not been found.

Diabetes Mellitus in Childhood. By Dr. A. C. Cotton.—The author reported a very interesting case and called attention to the care with which these cases should be managed. He also pointed out the importance of examining the urine as a part of the routine practice in the diagnosis of the disorders of childhood, so rarely done by the average physician. This perhaps accounted for the seeming rarity of this disorder in young children. That heredity played a rôle in the predisposition of diabetes there seemed to be little doubt. It seemed to the writer that the inclination of many to attribute to the infectious diseases of childhood a causal relation to diabetes was not based upon careful analysis of the evidence and that the glycosuria following such diseases was usually of the transient class. The advanced case of diabetes presented a picture of extreme inanition, emaciation, muscular weakness, dry skin and hair, brittle nails, extreme irritability, and extreme sensitiveness to cold, while the urinary symptoms were always present. Furunculosis and other skin lesions rarely appeared in children. No routine treatment was applicable to even the majority of cases. At the present time the regulation of the diet seemed to be the most important therapeutic measure. The death certificate followed hard upon the diagnosis and the rate of mortality was very high. Elimination was most important in these little patients, while they should be protected from mental strain, shocks, frights, trauma, and exposure to inclement weather. The importance of an early diagnosis was evident since success in treatment bore an inverse ratio to the previous continuance of the disease. Too much stress could not be laid upon the importance of always

protecting the child from any sudden lowering of the temperature.

Discussion.—Dr. C. F. Wahrer emphasized the view that medical treatment had little or no influence on the progress of diabetes, nor could much more be expected from the diet. Both might have some effect in improving things and holding the disease in check, but not in curing it. He could not recall any cases in which patients under ten years of age had recovered. Why should we take away from the patient, he asked, things that he could eat and insist upon him eating things that it took a strong adult stomach to digest? We should not commit ourselves to a routine treatment that might do more harm than good.

Albuminuria in Infancy and Childhood. By Dr. John R. Rathmell.—Diseases of the kidney in infancy and childhood are chiefly hyperæmias and nephritis following the contagious diseases, especially scarlet fever. Physiologically, albuminuria may occur at any period of infancy and childhood. It is most common between the ages of five and fifteen years and rarely persists; while albumin in the urine does not necessarily indicate serious organic disturbance in the kidney, yet its presence, in however slight a degree, demands the utmost watchfulness and care. Albumin is found in the urine after a rich meal, heavy muscular exertion, intense emotion, and cold bathing. Even when every other constituent of the urine is normal and functional albuminuria can be put aside, yet these cases require the most careful consideration, for, sooner or later, it may be after months or years have passed, grave lesions may show themselves, and we wake up to the fact that insidious degeneration has been going on in the meantime. It is very important, therefore, to decide whether the albuminuria is simply functional or is due to organic change. The prominent symptoms are albumin, high specific gravity, and œdema. These symptoms are especially found in interstitial and chronic parenchymatous nephritis, active hyperæmia, catarrhal nephritis, parenchymatous degeneration, passive hyperæmia, and acute nephritis. In acute nephritis the amount of albumin depends upon the extent of involvement of the glomeruli, and the amount of casts depends upon the extent of tubules affected. To meet the symptoms of œdema and ascites and treat them requires some thought concerning the condition of the patient. When threatening uræmia exists, diaphoretics, diuretics, and cathartics are indicated. Podophyllin, compound jalap powder and other watery purges may be used. Hot baths and hot packs should be used to cause profuse sweating where ascites is extreme and tapping is of value. For stimulation, teaspoonful doses of infusion of digitalis every four hours for a child five years old may be given. (To be continued.)

AMERICAN ACADEMY OF MEDICINE.

Twenty-sixth Annual Meeting, Held in St. Paul, on Saturday and Monday, June 1 and 3, 1901.

The following were among the papers read at this meeting:

The First-year Medical Curriculum. By Dr. Thomas D. Davis.—The author refers to the changes in the past few years in all medical courses. The change from a three-year to a four-year course is not necessarily an advance in medical education and there is an absolute necessity for higher admission requirements. The graduate in arts and sciences should have some advantage over those whose

preliminary education stops with the high school. The first year in the course in medicine should approach the last year in college. There are many of the college studies that are a great advantage to the medical man, especially logic, psychology, botany, and rhetoric.

SYMPOSIUM ON RECIPROCITY IN MEDICAL LICENSURE.

Is the Demand for Reciprocity Based upon Fact or Fancy? By Dr. Charles McIntire.—This paper is mainly an examination of the reports of various State boards of medical examiners to determine what percentage of physicians desire to remove from one State to another.

The Desirability of Reciprocity in Medical Licensure. By Dr. J. N. Hall.—The author refers to the fact of many physicians of excellent reputation wishing to locate in Colorado on account of their health or for personal reasons. These men are often men of experience and well fitted to practise medicine, but are rusty on the foundation studies, such as anatomy and physiology. Reciprocity would be of benefit to these men, but reciprocity should not be established except among those States whose requirements are essentially equivalent.

Reciprocity in Medical Licensure from the Standpoint of a Physician who Changes his Residence. By Dr. Edward Jackson.—About one in every four or five physicians changes his residence from one State to another some time in his career. Some give up the practice of their profession on account of the difficulties involved in such a change. The difficulty is not with the practical branches, which they are constantly in the habit of using, but rather with the preliminary studies, such as chemistry, anatomy, etc., whose technicalities they do not feel able to pass a stringent examination upon. The physician who wishes to remove cannot be expected to keep better posted upon those branches than he who does not wish to remove. The acceptance of the certificate of another State board as evidence of a proper acquaintance with such studies would remove the chief hardship. The fear of lowering the standard seems to be the greatest obstacle in the way. The standard in many States is placed "so high" that evasion in the form of special legislation lets in all sorts of irregular practitioners and threatens the permanence of medical practice laws.

Away with Reciprocity. By Dr. Charles McIntire.—The author thinks reciprocity will perhaps lead the profession far astray. Physicians already possessing the legal qualifications to practise medicine in one State should have certain privileges granted them in removing to another State. These privileges should be both fair to the people of the State as well as the physician, and the physicians already practising in that State.

SYMPOSIUM ON INSTITUTIONALISM.

Institutionalism: What is it? By Dr. Elmer Lee.—The Church was the first to start refuges for the sick and the afflicted. It was followed by corporate systems, State charities, and private enterprises. The individual fits himself for dependence by vicious habits and ignorance of knowing how to care for himself, also by misdirected energies and misfortunes. The author describes the classes that apply for institutional charities, and mentions some of the abuses connected therewith.

The Soul of Institutional Oversight. By Dr. John Curwen.—Under the present organization of society there is a necessity for institutions for the care of certain of the defectives. In order to protect society and to care for these defectives, it is necessary that the State give its aid to properly accomplish it.

Abuses of Institutionalism. By Dr. Eugene C. Carpenter.—Institutionalism is an outgrowth of organization. The result is routinism. Routinism begets perfunctoryism, which leads to automatism. Automatism is not different from that which is mechanical. Mechanical action is in fixed lines and does not depend upon experience and reflection. Opposition to innovations follows such action and is therefore opposed to progress. The result is that the institutionalist is dominated by the institution instead of dominating it, and so becomes its victim. The true institutionalist must always remain master of the institution and strive to keep out of too strict routinism. If he is narrow, all the participants in the institution will follow his narrowness. His policy, therefore, should be one of broadness and liberality, so that the institution may be known for its progress and breadth of purpose.

Tendencies in Hospitals for the Insane, with some Suggestions. By Dr. J. E. Robbins.—The author points out that too much isolation and lack of competition tend to make an institution inefficient. The medical staff is liable to become ultraconservative and the employés of all grades degenerate. It is necessary to keep in touch with the outside world and prevent the caste spirit of estimating men and women by themselves and not by their positions.

The Advantage of Civil Service Principles in the Conduct of the Insane Hospitals.—Dr. Gersom H. Hill read a paper with this title in which he describes the plan of the organization of the State institutions in Iowa, and treating of the benefits resulting from the system and the principles underlying it.

Evils in some Hospitals and Nurses' Training Schools that Might be Avoided by Proper Requirements, Regulations, and Inspections by the Board of Health of Each State. By Dr. Albert Goldspohn.—It is important that the administrative body of hospitals, asylums, etc., should be composed of both laymen and medical men. Competition is one of the greatest evils of the hospital system. The author also enters into the question of How can the abuse of medical charitable service in hospitals be reduced and regulated?

The Need of National Cooperation in the Establishment of Sanatoria for Tuberculosis. By Dr. A. Mansfield Holmes.—Sanatoria increase the chances for recovery and afford an opportunity for the carrying out of rigid sanitary regulations, which they do not have at home. They also educate the friends of those infected against the source of the infection, and thus prevent the spread of the disease. Sanatoria should be graded so as to suit those for whom they are instituted. They may be conducted entirely for profit or on the cooperative plan, or purely for charity alone. They may be located in climates known to possess beneficial influences or near large centres of population. The State could not direct its energies into a more useful channel than in the establishment and maintenance of sanatoria for tuberculosis.

Hospitals and Sanatoria Founded, Owned, and Controlled by the Medical Profession: A Case in Hand. By Dr. H. Bert Ellis.—The author divides hospitals into three classes—charitable, private, and mixed—and describes these classes and another owned and controlled by physicians alone. For the latter plan he claims many advantages and commends its adoption to physicians.

Institutional Life for Epileptics and for the Feeble-minded. By Dr. A. C. Rogers.—The family is unable to cope with certain abnormal conditions found in the life

of epileptics. These can only be properly managed in institutions. The organization, equipment, and management of these institutions should have in view the necessities and requirements of the particular class of people for whom they are intended. All institutions are remedial, custodial or a combination of the two. The community life is necessary for the feeble-minded and the epileptics in order to supply the variety of physical, mental, moral, and religious opportunities suited to their needs amid the most home-like conditions.

The Care of Epileptics in Massachusetts. By Dr. Everett Flood.—This paper is a history of institutional care of epileptics in Massachusetts, dealing more especially with statistics and the administration of the institutions.

A Suppressed Educational Problem. By Dr. James A. Taylor.—The author urges an "enlightened" natural selection in lieu of the ignorant, haphazard methods of selection practised by the majority of people, which result so generally in physical as well as intellectual deterioration.

Necessity for Revising Medical Fees. By Dr. P. Maxwell Foshay.—Medical services are not adequately remunerated, and a plea is made for changing the method of computing the value of professional services. The custom of charging a fixed sum is a relic of antiquity and is illogical. Charges should be made according to the importance of the service rendered, as is done in other callings. The greatest advantage would be the removal of all conditions that at present serve as an excuse to justify the offering of commissions by the surgeon and the specialist.

The Relation of the Clinical Laboratory to its Hospital. By Dr. Henry W. Cattell.—The author discusses this paper from a personal experience of twelve years and intimate connection with hospitals during that time in various capacities.

Letters to the Editor.

THE PRINCIPLES OF THE PHYSIOLOGICAL STANDARDIZATION OF DRUGS.

DETROIT, MICH., May 9, 1901.

To the Editor of the *New York Medical Journal*:

SIR: In his very excellent and scientific paper in the *Journal* for February 9, 1901, Dr. Leon L. Solomon makes some remarks upon the subject of physiological standardization of drugs which, to my mind, indicate that the gentleman is laboring under a misconception of the *rationale* of this, the only available method for estimating the medicinal worth of certain powerful drugs.

The writer says: "Conclusions concerning pharmacodynamics are reached with experiments upon animals or fowls *invariably* in a state of more or less perfect health; and these conclusions are intended to afford the student and practitioner of medicine a definite idea of the action to be expected from the same drug when administered in the same dose to a human patient, the latter presumably an individual with deranged secretions and in a pathological state."

The first statement is substantially correct; only healthy animals are employed in making physiological tests. The second statement is entirely erroneous. The

action of a drug upon a healthy animal and the action of the same drug upon a human being, in health or disease, may be similar, or they may be dissimilar to the extent of marked contrast. It is not to be presumed that the effect of a definite dose of any drug upon the frog or the cock will yield the same or similar results, in the same or any other dose, in human beings, sick or well. The results may be and often are similar, but such is not the case invariably.

Proceeding along the same line of argument, the writer says: "From the effect obtained by the administration of one fourth of a grain of morphine sulphate, for instance, to a healthy dog (or even to a healthy man) we are left to gauge the probable effect that will be obtained when the same dose of one fourth of a grain is administered to a person suffering let us say, from renal colic."

It so happens that opium is one of the drugs which can be standardized by chemical assay. Its alkaloid, morphine, when pure, may be expected always to yield a definite result. I say always, making due allowance, of course, for personal idiosyncrasies, because I do not know of any medicinal agent that yields more uniform physiological or therapeutic results. What these results are, and how exact they are, the physician is presumed to know. With whatever effect the drug has upon the dog, in this case, the physician has nothing to do. That need not concern him, because we are not obliged to standardize morphine physiologically. Pure morphine is always morphine; half a grain of one brand of pure morphine will have precisely the same effect as half a grain of another make, equally pure. The question which confronts the clinician at the bedside in a case of renal colic is not "Will one half grain of A.'s morphine relieve this pain, or shall I use B.'s?" The question is "How much *morphine* shall I give?" and the answer must be evolved from the physician's practical knowledge of the disease and its indicated remedy.

To quote again, the author of the paper under discussion remarks: "A thirty-drop dose of fluid extract of ergot must act identically in the case of post-partum hæmorrhage as it does on the bright red comb of a healthy young brown leghorn hen." Truly, it would appear that the doctor has set up a man of straw for the fun of knocking him down. *Good* ergot will cause contractions of the uterine muscle and blacken the comb of the leghorn fowl. *Poor* ergot will do neither. Each effect is a metric indication of the quality of the ergot. It is not necessary that the effect should be the same in both cases. The physician has the assurance, however, that a specimen of ergot that will blacken the cock's comb *will also cause uterine contractions*. Conversely, a specimen that fails to produce the former effect may be safely assumed to be therapeutically valueless. Is it not wise, therefore, to test our ergot upon cocks before we submit it to the arduous test of administration in a case of post-partum hæmorrhage, when a valuable human life may be at stake? Although this drug produces dry gangrene of the cock's comb, is it true that it "must act identically in the case of post-partum hæmorrhage"? (*Sic.*)

The situation may be stated thus:

First.—It is manifestly better and more scientific practice to administer to our patients standardized preparations only; *i. e.*, preparations whose strength has been fixed by some reliable method. Otherwise their strength must be determined by the physician. How? Upon

the body of his sick patient—a veritable physiological test—but under circumstances often of grave danger.

Second.—Many preparations can be standardized by chemical assay; that is, by estimating the amount of active principle which they contain and, by suitable corrections, making them conform to fixed standards of strength.

Third.—A number of the more important drugs, such as ergot, cannabis indica, digitalis, strophanthus, aconite, and others cannot be chemically standardized. There is no room for disputation upon this point. It is impossible to make a reliable chemical estimate of their medicinal value. How, then, shall their activity be tested? Manifestly upon animals.

I shall not consume time and space in discussing the first and second propositions. The third interests us most. A question now arises: Do these drugs, not amenable to chemical assay, produce the same effects on animals as on human beings? Some do, others do not. For the purpose of a physiological test, it makes no difference what their effects may be upon animals, so long as those effects are characteristic, constant, and capable of definite estimation. Under those conditions *they serve as tests of the physiological activity of the drugs*. From the results thus obtained it is perfectly proper and scientifically correct to assume that any drug which manifests a predetermined, characteristic, physiological effect upon a selected animal or group of animals may be placed in the hands of the physician with the assurance that it can be depended upon to yield its reputed therapeutic effects.

Finally, I must enter a protest against the statement that "the conclusions are invariably reached along false lines." They are reached on accurate scientific lines, and in the only available manner known to us. It is useless to discredit physiological standardization in the hope that eventually we may study drugs by "a consideration of their influence as exerted in diseased states." Imagine the manufacturer being compelled to determine the value of each lot of ergot which he produces in actual cases of post-partum hæmorrhage! Our knowledge of ergot in general might be and has been enriched by clinical study, but it should be borne in mind that whatever method of standardization we adopt must be practicable. Every single pint of fluid extract which the maker puts out must be subjected to some practical test of its activity.

Physiological standardization is one of the landmarks of modern medical progress, and without its beneficial aid the practitioner would be groping in the dark, so far as certain important drugs are concerned, as did his predecessor of a century ago.

CUVIER R. MARSHALL, M. D.

Miscellany.

The Right to Expectorate.—A correspondent of the *Medical Press and Circular* for June 5th says that, on reading a leaderette on the above subject in the *Medical Press and Circular* of May 29th, he is tempted to ask why spittoons are not provided for the convenience of the public, more especially in the States, where promiscuous expectoration is punishable by law. The Sal(i)-vation Army, he says, should naturally take the lead in this movement, which, of course, would not apply to

such a district as Spitalfields. He is inclined to think that the only portion of the public having the right to promiscuous expectoration are town councillors, who only expect a rate once a year. [To which we may add that the writer must expect irate remonstrances for his bad habits of speech.]

The Nerve and Vascular Associations of the Kidneys.—Edmund Owen (*Lancet*, June 8th), in an address recently delivered before the Cardiff Medical Society, said that in a large proportion of cases of renal disease the most prominent symptom was the subjective one of *pain*. At any rate, it was usually this which brought the patient to the surgeon, and made the latter set to work to discover objective signs which might lead him to a correct conclusion as regarded its cause. In speaking of the anatomical associations of the kidney, therefore, particular attention must be paid to the nerves, which not only associated the kidney with the neighboring parts, but also kept the kidneys in harmonious working with each other. The nerves were derived from the sympathetic plexus in front of the upper part of the abdominal aorta, and into this plexus ran branches of the splanchnics, the pneumogastrics, and also, indirectly, of the spinal nerves. These various filaments joined in an entanglement from which the instruments of the most skilled dissector were unable to sort or to unravel them, and each abdominal viscus took filaments from this interlacement according to its needs. Remembering that the testis was developed in close association with the kidney, it was not surprising that the nerves of the renal plexus were intimately connected with those of the spermatic plexus. And to this association of nerves was due the explanation of the pain in the testicle to which renal calculus often gave rise.

With an innervation scheme, in which medullated and sympathetic filaments were thrown with ganglia into a central pool from which each viscus helped itself, as it were, it could hardly be matter of surprise if the result did not always work out quite satisfactorily in a clinical sense, and when disturbance arose in the affairs of any individual viscus, confusion was apt to occur, and errors of diagnosis and treatment were apt to ensue in consequence. Supposing that a calculus was forming in one kidney, a somewhat urgent and disquieting message was transmitted to the solar plexus. This was an unwonted occurrence, and the plexus was unprepared for its reception and incompetent to deal with it. All was muddle and confusion, and when an explanation was demanded as to why and where the disturbance arose, and as to the precise cause of it, answer came that it was on this side or on that side—it might be right and it might be wrong. In the clinical case related the answer was as incorrect as it could be:

"A healthy-looking man, thirty-six years of age, was admitted to St. Mary's Hospital on October 7, 1897. The notes say that he first felt dull pains in his back ten years previously, and that about five years later he had a bad attack of renal colic on the left side; that he had several like attacks each year (which were always associated with vomiting), and that he had passed blood and many small calculi on various occasions. For the purpose of this paper, I wrote the other day to the patient for his own account, and this is what he said: "These later attacks were very severe and always confined to the right side, and relief was only procurable by apply-

ing linseed poultices and turpentine to the back and then to the front, the marks of which were on me when I was examined.' Yes, this was so; at the time of his admission the skin of the front and back of the right renal region was deeply stained by the marks of fomentations, and the patient was quite satisfied in his own mind that the small calculi, which he had passed from time to time, had come from the *right* kidney. Objective signs gave no help in the matter of localization. On October 13th the bladder was sounded, with a negative result, and a few days afterward I explored the right kidney from behind, finding it larger than normal, but otherwise healthy. The patient, a highly intelligent man, was, like myself, a good deal disappointed at this blank operation; but he promised to come into hospital again in a few weeks, so that I might explore the other kidney. . . . He came back toward the end of the following month, saying that since the operation he had been 'perfectly comfortable,' but that on one occasion he had passed some blood. On November 29th I cut down upon the posterior surface of the *left* kidney, extracting a branching, coral-like calculus and several small calculi, and also evacuating a renal abscess of considerable size. The stone was phosphatic, and it weighed over 400 grains. Seeing how extensively this kidney was diseased, I hesitated whether I should take it away or not, but eventually decided to give it a chance. So I deluged its interior with hot sterilized water, and in this way washed out some more small stones. A drainage-tube was introduced into the kidney and the surface wound was closed. While in the hospital the man occasionally passed small calculi *per urethram*; his urine contained some pus and at times a little blood. There was, moreover, constant leakage from a sinus which persisted in the loin. He left the hospital in January fairly well, except for the annoying sinus. This sinus continued to leak, so he came into the hospital again in February, 1898, in order that I might relieve him of that annoyance by removing the kidney. But when I examined him under an anæsthetic, and had explored the kidney with my finger, I had not the heart to perform the nephrectomy, as I found that a considerable amount of firm and apparently healthy tissue still remained. So I chased out a few more small stones, and determined to give the damaged organ yet another chance. The man stayed only a few days in hospital, and shortly afterward resumed work at the bank, where he continued at business for a little over a year, the sinus oozing all the time into pads of absorbent dressings. To use his own words, 'After the Easter holidays, 1898, I continued daily to travel up and down to the city, without a single exception, changing the bandage at midday, and on going to bed my wife used to thoroughly wash and irrigate the wound and to pass a probe down. I never became offensive, and I had fairly good health until April, 1899. Then I came to see you, when you immediately operated, and removed the kidney, April 17, 1899, after which the wound healed completely.' He is now perfectly well, his large right kidney being quite up to the work thrown upon it—even after a twenty-five-mile bicycle ride."

An interesting feature of this case, Mr. Owen continued, was that, though the man was working in a city office through the hot months, his fellow clerks never noticed any unpleasant odor; if an intelligent man with a renal fistula took care of himself, his wound need not become septic or his leaking urine offensive.

Mr. Owen was well aware that it was not a very unusual occurrence for a surgeon to operate upon the wrong kidney in his search for a stone, but he did not think that a more conspicuous instance than this, of the untrustworthiness of the subjective symptom of *pain* in renal calculus, was likely to be forthcoming. Subjective signs were proverbially untrustworthy through the whole range of surgery; but in the case of the kidneys, which had drawn their nerves blindfold from the epigastric pool, it was small wonder if, in the absence of objective signs, patient and surgeon were sometimes led by them to make serious mistakes.

In one matter in particular the vascular associations of the kidney were important from a surgical as well as from a medical point of view. Take, for instance, the case of a man with old-standing stricture of the urethra, that was to say, a surgical case of damaged kidneys, or a man with early Bright's disease—a sufficiently vague term. The kidneys were just able to do the amount of excretory work demanded of them, but they had absolutely no reserve of physiological energy. If the man indulged in a drinking bout, or, out of work, he got wet through, and was suddenly attacked with sub-acute nephritis, and, perhaps, with complete suppression of urine, what was to be done for him? The intestinal canal and the skin were always ready to assist the kidneys if properly called upon, and, therefore, a full dose of calomel and jalap and a hot-air bath might suffice to help the comatose patient over this very serious crisis. But there was something yet that might be done toward relieving the vascular engorgement of the kidneys and putting them in working order once more. The practitioners of bygone days would have resorted to venesection, and Mr. Owen was not sure that he would not do so himself, for he was a keen advocate for this "old-fashioned remedy out of date," as the late Dr. Hare called it. But the method to which he desired to refer was the application of a score of leeches or the efficient employment of wet or dry cupping over the loins.

In his valuable work upon *The Arteries*, published in 1828, Robert Harrison specially called attention to the fact that the lumbar branches of the aorta helped in the supply of the kidneys—that was to say, that a free communication took place between the vessels of the abdominal wall and those of the abdominal viscera. Sir William Turner, also, in the *British and Foreign Medico-chirurgical Review* of 1843, gave an account of the parietal and visceral anastomoses from diaphragm to perineum. He found that the renal artery from the abdominal aorta, having given the kidney all that it needed, sent branches through the fibrous capsule to join in an extensive anastomosis, which Turner named the sub-peritoneal arterial plexus. The chief vessels in this anastomosis of parietal with visceral arteries were the phrenic and the lower intercostal arteries and the upper lumbar branches of the aorta. Together with this arterial anastomosis there was a free communication between the venous plexus of the parietes and that of the kidney. And thus it came about that the application of leeches or cupping glasses to the loins had an equally direct and important influence in the relief of renal engorgement. A knowledge of this piece of anatomy explained, moreover, how it was that a turpentine fomentation or a mustard plaster, by causing a dilatation of the surface capillaries and getting them filled from the renal vessels, thereby relieved the congestion of the kidneys, and produced a valuable diuretic effect.
